Generally, the tooling structure—the interface between the cutting tool or insert and the machine tool—is the weakest link in a machining system.²⁰ In many cases, the tooling structure is the bottleneck concerning the achievable accuracy imposed by static deflections and the cutting regimes as well as the surface finish due to forced and self-excited vibrations. For instance, long-overhang cantilever tooling is frequently the critical part of the tooling structure. In the case of tooling based on steel bars the upper limit for stable machining with a reasonable machining regime is generally considered to be $L/D = 4$, where L/D = bar overhang/bar diameter.^{20–22} But in more demanding applications, such as internal threading and grooving, vibrations may start at an overhang between two and three times the bar diameter.²²

Basically, all methods for improving the tooling structure concern modifications of the tooling structure's dynamic stiffness and/or balancing of rotating parts of the tooling structure.^{18,20–28} All the elements and joints in the chain from the tool or insert to toolholder–clamping—machine or toolholder—spindle interface have been addressed with the purpose of enhancing the chatter resistance of machine tools. The

trend of continuously increasing requirements on speed and accuracy has also turned the focus toward the balancing of tool holders for rotating tools.²⁰

Methods for reduction of vibration and chatter comprise the increase of the damping and/or stiffness of insert or tool attachment systems, the reduction of the toolholder stiffness to enable the tool to retract out of the workpiece when the dynamic cutting force increases, the increase of the dynamic stiffness of toolholder shanks by means of passive or active control methods, the reduction of the stiffness of the toolholder shank while increasing the damping of the clamping, the improvement of the dynamic stiffness of the interface between tool and clamping device, the improvement of the dynamic stiffness of the tool clamping devices/spindle connection, the active and passive balancing of toolholders for rotating tools, and the like.²⁰

3.1 Control Strategies

Two main directions have evolved for the control of machine tool chatter: one concerns the selective modification of the dynamic stiffness of the tooling structure^{18,20–28}; the other concerns the control of cutting data to maintain stable cutting, that is, to avoid cutting data resulting in chatter or to continuously vary cutting data in a structured manner to avoid chatter.^{20,29,30}

In the reduction of forced unbalance vibration in rotating tooling structures two basic balancing concepts are passive balancing systems, both offline and online (self-balancing), and active online balancing using sensors and actuating devices on the rotating component.²⁰

3.2 Passive Control

Generally, increased dynamic stiffness is associated with passive vibration control. However, successful application of turning toolholders, boring bars, and face milling cutter with selectively reduced static stiffness in the primary direction have been achieved for enhanced chatter resistance.^{1,20,31} This will enable the tool or tools to retract out of the workpiece—reducing the effective chip area—when the dynamic cutting force increases.^{1,20}

The improvement of the chatter resistance of tooling structures usually involves a static stiffness reduction simultaneous with an increased damping of the tooling structure, that is, an enhancement of the dynamic stiffness and stability.^{1,20,22,32,33} This method has, for instance, been utilized successfully in clamping devices for drilling, in a tool clamping for external longitudinal turning in the direction normal to the workpiece, in grinding wheels, in boring bar clamping devices, and the like.^{20,32,33}

The long-overhang cantilever tooling is frequently the critical part of the tooling structure, and several passive techniques have been implemented within the boundaries of these cantilever structures. These passive methods are well-known to enhance the dynamic stiffness and stability (chatter resistance) of long cutting tools and, thus, enables the allowable overhang

to be increased.^{20,22,23} A common way of increasing the dynamic stiffness of cantilever tooling is by making them in high Young's modulus nonductile materials such as sintered tungsten carbide and machinable sintered tungsten.^{20,22,23} Solid bars made of both these materials allow stable cutting with ratios $L/D < 7$.^{20,22} The dynamic stiffness of cantilever tooling may be further increased at the cost of reduced static stiffness by, for example, implementing a tungsten carbide rod inside a tube-formed boring bar.²⁰ The boring bar design with an internal tungsten carbide rod can cut chatter free at a depth of 15 to 30% greater than a solid carbide bar of the same diameter at $L/D = 6.5$.²⁰

At present, the most common approach to enhancing the dynamic stability of long cantilever tooling is the application of an widely used method for vibration suppression; the passive tuned vibration absorbers (TVA).^{20,22,23} In the literature the tuned vibration absorbers are also refereed to as tuned mass dampers (TMD) or dynamic vibration absorbers (DVA). A TVA is usually implemented in a tube form, for example, boring bar at the tool end. A cylindrical damper body may, for example, be coupled to the bar via rubber rings at each end of the cylindrical damper body with damper oil in between the rubber rings^{20,22,23}; see Fig. 4. The placement of the tuned vibration damper at the tool end enables the greatest control force into the fundamental bending modes.³⁴ The absorber is tuned to a given frequency range by adjusting the weight of the reactive mass and the stiffness and damping properties of the elastic element. The vibration absorbers are tuned either to a tonal or a broadband application.

Steel boring bars with TVAs allow stable cutting with ratios $L/D < 10$.^{22,23} The performance of TVA boring bars may be improved further by making the root segment of the bar closest to the clamping of

Figure 4 Passive damped boring bar.^{20,22,23} (a) Heavy tuning body. (b) Rubber ring. (c) Damper oil.

high Young's modulus materials such as sintered tungsten carbide and machinable sintered tungsten.^{20,22,23} Carbide-reinforced TVA boring bars enable stable cutting with ratios $L/D < 15$.^{20,22,23}

3.3 Active Control of Chatter — A Promising New Development

Active vibration control of machine-tool vibration comprises a number of different methods for introducing the control force into fundamental bending modes of toolholder shanks; it also includes different controller approaches. As the original excitation of the tool vibrations—the chip formation process—cannot be directly observed, the control methods are all based on feedback control.^{18,24–28} Figure 5 shows a machine-tool feedback control system.

One of the approaches concerns the adaptive active control of tool vibration using embedded and integrated actuators adjacent to the clamping below the centerline of holder shanks for external turning and boring bars controlled by the feedback filtered-x LMS algorithm.^{24,25} Figure 6 shows control results

Figure 5 Machine-tool feedback control system.

Figure 6 (a) Power spectral density (PSD) of boring bar vibrations with and without feedback filtered-x LMS control. Cutting speed $v = 80$ m/min, cutting depth $a = 1.5$ mm, feed rate $s = 0.3$ mm/rev, DNMG 150608-SL, grade 7015. (b) Power spectrum of the absolute-calibrated sound pressure level excited by tool vibration in external longitudinal turning with and without feedback filtered-x LMS control. Cutting speed $v = 80$ m/min, cutting depth $a = 0.9$ mm, feed rate $s = 0.23$ mm/rev, DNMG 150608-SL, grade 7015.

for a toolholder shank and a boring bar produced using this method.

Another method for active control of boring bar vibration involves LQ control³⁵ and piezoelectric inertial-mass actuators mounted at the tool end.²⁶ Also, a control approach based on active clamping and the feedback filtered-x LMS algorithm for boring bars has been developed. The active clamping consists of two actuator pairs: one pair for the introduction of the control force in the cutting speed direction and one pair for the introduction of the control force in the cutting depth direction.²⁶ An active spindle unit for the control of tool vibration in milling has recently been developed.²⁸ Two actuator pairs introduce secondary vibrations into two orthogonal radial directions into the spindle.²⁸ The actuators are steered by an LQG controller³⁵ fed with strain gauge signals that senses the bending motion in the spindle-cutter assembly.²⁸

3.4 Cutting Data Control

Cutting data, feed rate, and cutting speed may also be controlled to maintain stable cutting. Control can, for example, be carried out on the basis of estimates of the damping ratio of a relevant natural frequency of the joint dynamics of the cutting process and of the machine tool structure using an ARMA model with recursively estimated parameters.²⁹ Other approaches including continuous variation of the cutting speed to maintain stable cutting have also been suggested. The amplitude and frequency of a sinusoidal spindle speed variation may be controlled with respect to minimum energy input by the cutting process based on knowledge of the spindle speed and the chatter frequency.³⁰

1 INTRODUCTION*

The sound power level is the measure of the sound power radiated by a sound source expressed in a logarithmic scale relative to 10^{-12} W with a unit of decibels. Procedures for calculating the sound power level of industrial machinery are presented in this chapter. The calculated sound power levels can be used for modeling the sound pressure levels in a space or developing purchase specifications for new equipment.

With any project, acoustical data measured and calculated in accordance with recognized standards should be obtained. Many manufacturers provide sound power levels or measured sound pressure levels at 1 m from their equipment, and some offer special low-noise options. If manufacturer's data is unavailable, efforts should be made to measure a similar unit in operation. If this is not practical, then the material in this chapter can be used.

Most of the equations presented in this chapter are based on measured data and tend to be conservative, usually predicting somewhat higher sound pressure levels than are measured in the field. Due to recent efforts at reducing equipment noise, sound pressure levels for some equipment may be significantly (10 dB) quieter than the levels calculated in this chapter.

Some equipment consists of several different sound-producing components such as motors, pumps, blowers, and the like. The sound power levels for each component should be determined and then combined (using correct decibel addition) to get the total sound power levels.

*Much of this material was published earlier as Chapter 86 of Volume 2 of *Encyclopedia of Acoustics*, John Wiley & Sons, Inc. 1997, which utilized formulas from several references, especially Ref. 1. In this chapter, some formulas have been modified to use metric units and to give the A-weighted sound power level directly from the equipment parameters.

2 POWER SOURCES

2.1 Boilers¹

Main Steam Boilers Main steam boilers of a power plant radiate igniter, flow, and combustion noise from their surfaces. The A-weighted sound power level for main steam boilers (between 125 and 800 MWe) can be calculated using Eq. (1) where MWe is the electrical generating rating of the unit. The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 72 + 15 \log \text{MWe} \quad \text{dB} \quad (1)$$

Auxiliary Boilers The noise produced by auxiliary boilers is often due primarily to the blower and the burner, not the walls of the boiler. An estimate of the A-weighted sound power level for auxiliary boilers between 0.5 and 20 MW can be calculated using Eq. (2). The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1. For boilers rated in other units, 1 MW = 102 bhp = 1600 kg steam/h.

$$L_W = 94 + 4 \log \text{MW} \quad \text{dB} \quad (2)$$

2.2 Electric Motors

Motors under 750 kW² Totally enclosed fan-cooled (TEFC) motors are the most common type of electric motors. They are generally cylindrical in shape with a fan at one end, the output shaft at the other end, and fins along the body. The A-weighted sound power level for TEFC motors can be calculated using the following equations:

$$\begin{aligned} < 40 \text{ kW} : L_W = 16 + 17 \log \text{kW} \\ &+ 15 \log \text{rpm} + 10 \log S \quad \text{dB} \quad (3) \end{aligned}$$

$$\begin{aligned} \geq 40 \text{ kW} : L_W = 27 + 10 \log \text{kW} \\ &+ 15 \log \text{rpm} + 10 \log S \quad \text{dB} \quad (4) \end{aligned}$$

Table 1 Octave Band Sound Power Level Adjustments

Source	31.5	63	125	250	500	1000	2000	4000	8000

^a Equations (29)–(32) are for the unweighted sound power levels. Subtracting the values in this table will yield the unweighted octave band sound power levels. After making the adjustments described in the text for the blade passage frequency [calculated in Equation (28)], the A-weighted sound power level can be calculated.

where kW is the nameplate motor rating (1 kW = 1.34 hp), rpm is the speed at which the motor is operating, and S is the conformal surface area (in square metres) at 1 m from the motor (see the Appendix to this chapter for the equation for the conformal surface area). For TEFC motors between 300 and 750 kW, use the value 300 kW in Eq. (4). The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

For drip-proof motors, the A-weighted sound power level can be calculated using the following equations:

$$\begin{aligned} <40 \text{ kW: } L_W = 8 + 17 \log \text{ kW} \\ + 15 \log \text{ rpm} + 10 \log S \text{ dB (5)} \end{aligned}$$

$$\begin{aligned} \geq 40 \text{ kW: } L_W = 19 + 10 \log \text{ kW} \\ + 15 \log \text{ rpm} + 10 \log S \text{ dB (6)} \end{aligned}$$

For drip-proof motors between 300 and 750 kW, use the value 300 kW in Eq. (6).

The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

Motors between 750 and 4000 kW¹ The sound power level for large drip-proof electric motors (between 750 and 4000 kW) can be estimated by using Table 2.

2.3 Gas Turbines²

Manufacturers of gas turbines often have sound power level data for the exhaust and inlet. Obtaining accurate casing data can be difficult due to contributions from the inlet, exhaust, or other equipment. The A-weighted sound power level for gas turbines can be estimated using Eqs. (7) to (9). The unweighted octave band sound power level for each of these sources can be obtained by subtracting the values shown in

Table 2 Octave Band and A-Weighted Sound Power Levels for Drip-Proof Electric Motors (750–4000 kW)

Speed (rpm)	31.5	63	125	250	500	1000	2000	4000	8000	A
1800 or 3600	94	96	98	98	98	98	98	95	88	104
1200	88	90	92	93	93	93	98	88	81	101
900	88	90	92	93	93	96	96	88	81	101
<720	88	90	92	93	93	98	92	83	75	100
250 or 400 (vertical)	86	87	88	88	88	98	88	78	68	99

Table 1.

$$\text{Casing : } L_W = 118 + 5 \log MW \quad \text{dB} \quad (7)$$

$$\text{Exhaust : } L_W = 129 + 10 \log MW \quad \text{dB} \quad (8)$$

$$\text{Intake : } L_W = 127 + 15 \log MW \quad \text{dB} \quad (9)$$

2.4 Reciprocating Engines²

The major noise sources of natural-gas and diesel reciprocating engines are the engine casing, exhaust noise, radiator (fan) noise [see Eq. (32)], and for turbocharged engines, the air inlet. The sound power levels for each component must be determined. The component levels can then be added together (correct decibel addition) to determine the total sound power levels.

Engine Casing Noise The A-weighted sound power level for engine casing noise can be calculated using Eq. (10) where kW is the full-load rating of the engine, and *A*, *B*, *C*, and *D* are correction factors obtained from Table 3. The octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 90 + 10 \log kW + A + B + C + D \quad \text{dB} \quad (10)$$

Air Inlet For all naturally aspirated engines and for turbocharged engines under about 340 kW, the casing-noise calculation includes the air inlet noise. For turbocharged engines above 340 kW, the A-weighted

sound power level of the air inlet can be calculated using Eq. (11) where d_{inl} is the length of the inlet ducting in metres. The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 92 + 5 \log kW - (d_{\text{inl}}/1.8) \quad \text{dB} \quad (11)$$

Engine Exhaust The A-weighted sound power level for the unmuffled exhaust can be calculated using Eq. (12) where *T* is a turbocharger correction term (*T* = 6 if the engine has a turbocharger, *T* = 0 if there is no turbocharger) and d_{exh} is the length of the exhaust pipe in metres. The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 108 + 10 \log kW - T - (d_{\text{exh}}/1.2) \quad \text{dB} \quad (12)$$

2.5 Steam Turbines¹

Manufacturers of steam turbines often have sound pressure level measurements, but the levels may not have been measured in accordance with a recognized standard. The A-weighted sound power level for steam turbines can be estimated using Eq. (13), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 88 + 4 \log kW \quad \text{dB} \quad (13)$$

Table 3 Sound Power Level Correction Terms for Casing Noise of Reciprocating Engines

Correction Term	Qualifying Condition	dB
<i>A</i>	Less than 600 rpm	−5
	600–1500 rpm	−1
	Over 1500 rpm	2
<i>B</i>	Diesel and/or natural gas fuel	0
	Natural gas only (with small amount of "pilot oil")	−3
<i>C</i>	In-line cylinders	0
	V-type or radial cylinders	−1
<i>D</i>	Unducted air inlet to unmuffled roots blower	5
	All other types of inlets (with or without turbocharger)	0

2.6 Steam Turbine–Generator Units¹

The A-weighted sound power level for main steam turbine–generator units (between 200 and 1100 MWe) can be calculated using

$$L_W = 101 + 4 \log \text{MWe} \quad \text{dB} \quad (14)$$

The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1. Equation (14) takes into account sound contributions from the high- and low-pressure turbines, generators, and shaft-driven exciters. Noisy couplings and steam control valves can cause higher sound power levels than those predicted with this equation.

2.7 Transformers¹

Noise from the body of the transformer is made up of tones at the even harmonics of the line frequency. In the United States, where the line frequency is 60 Hz, the harmonics are 120, 240, 360, 480, ... Hz with the 120-Hz tone usually being the dominant sound. When additional cooling of the transformer is needed, noise from the cooling fans can become the dominant noise source. Lower fan speeds and optimal blade shapes have helped make newer fans much quieter, which is particularly helpful in noise-sensitive applications.

The National Electrical Manufacturers Association (NEMA) sound pressure level rating is the A-weighted sound pressure level 1 ft from the transformer and can be estimated from the following formulas:

Standard transformer:

$$\text{NEMA sound rating} = 55 + 12 \log \text{MVA} \quad \text{dB} \quad (15)$$

Quieted transformer:

$$\text{NEMA sound rating} = 45 + 12 \log \text{MVA} \quad \text{dB} \quad (16)$$

where MVA is the voltage–ampere rating of the transformer in MVA. These equations are valid for transformers between 20 and 450 MVA. The A-weighted sound power level can be calculated using

$$L_W = \text{NEMA sound rating} + 10 \log S \quad \text{dB} \quad (17)$$

where S is the surface area of the four side walls in square metres. The term $10 \log S$ may be estimated from the MVA rating by using

$$10 \log S = 14 + 2.5 \log \text{MVA} \quad \text{dB} \quad (18)$$

Unweighted octave band sound power and pressure levels can be obtained by subtracting the appropriate octave band correction factors shown in Table 1.

3 DRIVEN EQUIPMENT

3.1 Air Compressors

Centrifugal Compressors^{1,3} The frequency band of maximum sound power from the casing or discharge piping for large centrifugal compressors can be calculated based on the impeller tip speed, U , in metres per second ($30 < U < 230$):

$$f_p = 4.1U \quad (19)$$

The octave band sound power level in that frequency band can be calculated using Eq. (20) where m is the surface weight of the casing or pipe wall in kilograms per square metre and f is the octave band center frequency.

$$L_W = 20 \log \text{kW} + 50 \log U - 17 \log (mf) - 1.5 \text{ dB} \quad (20)$$

The adjacent octave bands above and below f_p roll off at a rate of 3 dB/octave. The A-weighted sound power level can be calculated from the octave band values.

If the tip speed is not known, the A-weighted sound power level for the casing noise of centrifugal compressors between 1100 and 3700 kW can be calculated using Eq. (21), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 77 + 10 \log \text{kW} \quad \text{dB} \quad (21)$$

The A-weighted sound power level for the unmuffled air inlet of centrifugal compressors can be calculated using Eq. (22), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 80 + 10 \log \text{kW} \quad \text{dB} \quad (22)$$

Reciprocating Compressors³ For reciprocating compressors, the fundamental frequency is calculated from the number of cylinders (B) and the speed as follows:

$$f_p = B \text{ rpm}/60 \quad (23)$$

The octave band sound power level in the frequency band containing f_p that is radiated from the casing or discharge piping for large reciprocating compressors can be calculated using Eq. (24) where m is the surface weight of the casing or pipe wall in kilograms per square metre and f is the octave band center frequency:

$$L_W = 150 + 10 \log \text{kW} - 17 \log (mf) \quad (24)$$

This equation assumes that the sound power is radiated from 15 m of discharge piping. The adjacent octave bands above and below f_p roll off at a rate of 3 dB/octave. The A-weighted sound power level can be calculated from the octave band values.

Rotary and Reciprocating Air Compressors¹

Equation (25) presents an alternative method for calculating the A-weighted sound power level of reciprocating air compressors based on just the kW rating. This equation can also be used with rotary compressors and includes the noise of partially muffled air inlets. The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 88 + 10 \log \text{ kW} \quad \text{dB} \quad (25)$$

3.2 Boiler and Reactor Feed Pumps¹

The A-weighted sound power level for large boiler and reactor feed pumps driven by motors or steam turbines can be estimated by Eqs. (26) and (27), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$1\text{--}9 \text{ MW} : \quad L_W = 83 + 7 \log \text{ kW} \quad \text{dB} \quad (26)$$

$$9.5\text{--}18 \text{ MW} : \quad L_W = -32 + 36 \log \text{ kW} \quad \text{dB} \quad (27)$$

3.3 Fans

Fan noise is produced primarily by airflow around the blades. Manufacturer's fan data is highly recommended due to significant variations in fan noise levels. The levels presented in this section assume a static efficiency of 95 to 100%. Sound pressure levels increase about 1 dB for every 3% reduction in the static efficiency from 99%.

Blade Passage Frequency Calculation¹ The blade passage frequency (BPF) for fans is calculated as follows:

$$\text{BPF} = (\text{fan rpm} \times \text{No. of blades})/60 \quad (28)$$

Centrifugal-Type Fans with Airfoil or Backward-Curved Blades¹ The unweighted sound power level of the inlet noise of forced-draft fans with inlet control vanes or the discharge noise of induced-draft fans can be calculated using

$$L_W = 10 + 10 \log Q + 20 \log \delta P \quad \text{dB} \quad (29)$$

where Q is the airflow in cubic metres per minute and δP is the pressure drop across the fan in pascals (newtons per square metre). The octave band sound power levels can be obtained by subtracting the values shown in Table 1 and by making the following corrections for the blade passage frequency [Eq. (28)]:

- For forced-draft fans used in high-pressure applications, add 5 dB in the octave band containing the BPF.
- For induced-draft fans, add 10 dB in the bands containing the BPF and its harmonic (twice the BPF).

The A-weighted sound power level can be calculated from the octave band values after making all of the corrections.

If there is ducting on the inlet to the fan, the unweighted sound power level of the uninsulated fan casing may be calculated using

$$L_W = 1 + 10 \log Q + 20 \log \delta P \quad \text{dB} \quad (30)$$

The octave band sound power levels can be obtained by subtracting the values shown in Table 1 and by adding 5 dB in the octave band containing the BPF [Eq. (28)] for high-pressure applications.

The noise generated at the uninsulated fan breaching (discharge ductwork) is approximately 6 dB lower than that generated by the uninsulated fan housing. The frequency spectrum is similar to that for the uninsulated fan housing. The A-weighted sound power level can be calculated from the octave band values.

Axial-Flow Fans¹ The unweighted sound power level of the inlet noise of forced-draft fans or the discharge noise of induced-draft fans can be calculated using

$$L_W = 21 + 10 \log Q + 20 \log \delta P \quad \text{dB} \quad (31)$$

The octave band sound power levels can be obtained by subtracting the values shown in Table 1 and by adding 6 dB in the octave band containing the BPF. The A-weighted sound power level can be calculated from the octave band values.

For vaneaxial fans, inlet guide vanes cause much higher blade passage noise than outlet guide vanes. These modifications will change the A-weighted sound power level.

Propeller Fans³ The unweighted sound power level of the inlet or outlet of a propeller fan with a diameter of 3.5 m or less can be calculated using

$$L_W = 60 + 10 \log Q + 20 \log \delta P \quad \text{dB} \quad (32)$$

The octave band sound power levels can be obtained by subtracting the values shown in Table 1 and by adding 5 dB in the octave band containing the BPF. The A-weighted sound power level can be calculated from the octave band values.

Gas Recirculation Fan Casing¹ The A-weighted casing sound power level for centrifugal fans used for gas recirculation service (1300 to 4100 kW) can be calculated using Eq. (33), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 1 + 10 \log Q + 20 \log \delta P \quad \text{dB} \quad (33)$$

3.4 Gears²

The following equation provides an estimate of the A-weighted sound power levels based on studies of gearboxes rated from 200 to 17,500 kW:

$$L_W = 86 + 3 \log \text{rpm} + 4 \log \text{kW} + 10 \log S \quad \text{dB} \quad (34)$$

where L_W is the A-weighted sound power level, rpm is the speed of the slower gear shaft, kW is the power transmitted through the gearbox, and S is the conformal surface area (in square metres) at 1 m from the gearbox (see the Appendix to this chapter for the equation for the conformal surface area).

The un-weighted octave band sound power levels can be obtained by subtracting the values shown in Table 1. The actual levels in the octave bands containing the gear-meshing and gear-ringing frequencies may differ from these estimates.

3.5 Generators³

The A-weighted sound power level for generators (not including the driver noise) can be calculated from Eq. (35), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 80 + 10 \log \text{MW} + 6.6 \log \text{rpm} \quad \text{dB} \quad (35)$$

3.6 Pumps²

The A-weighted sound power level for motor-driven pumps under 2000 kW can be calculated using Table 4. In this table, kW is the nameplate motor rating and S is the conformal surface area (in square metres) at 1 m from the pump (see the Appendix to this chapter for the equation for the conformal surface area). The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1. These equations are based on sound pressure level measurements at 1 m from the pump and therefore include some sound contributions from the driver and suction and discharge piping. For high-pressure applications, the level in the band that contains the blade passage frequency and its second harmonic may be 5 to 10 dB higher than the calculated levels.

4 VALVE AND PIPING NOISE

The sound pressure level produced by gas control valves is dependent on whether the flow through the valve is subcritical or supercritical (choked-valve

condition). For subcritical flow, the valve noise is due to turbulent mixing and turbulence–boundary interaction. For supercritical flow, the valve noise is due primarily to broadband shock noise.

Most valve manufacturers, such as Fisher or Masoneilan, have semiempirical models to predict the sound pressure level at a position 1 m downstream of the valve and 1 m out from the piping. These models are expected to predict the A-weighted sound pressure level to within 5 dB of the actual level. For situations when the manufacturer cannot provide data or as an alternative, Ng⁴ provides a control valve calculation procedure. All of these methods assume some number of straight piping sections downstream of the valve. The presence of a tee, mitered bend, or an elbow near the valve discharge can significantly increase the sound pressure level from quiet trim valves.

Turbulence generated in piping can also be a significant source of noise. CONCAWE^{5,6} and Norton⁷ have published procedures by which flow-induced sound power levels can be predicted. These procedures require a fairly detailed knowledge of the flow conditions and piping and are beyond the scope of this chapter. In general these procedures are expected to predict the A-weighted sound pressure level to within 3 dB.

5 INDUSTRY-SPECIFIC EQUIPMENT

5.1 Air Conditioning for Buildings

Cooling Towers¹

Mechanical-Draft Cooling Towers The A-weighted sound power level of mechanical-draft propeller-type cooling towers can be calculated using

$$\text{Full speed : } L_W = 86 + 10 \log \text{kW} \quad \text{dB} \quad (36)$$

$$\text{Half speed : } L_W = 83 + 10 \log \text{kW} \quad \text{dB} \quad (37)$$

where kW is the full-speed power rating of the fan. The octave band sound power levels can be obtained by subtracting the values shown in Table 1. When calculating sound pressure levels at distances greater than 10 to 20 m from the tower, the values shown in Table 5 should be added to these values to account for directional effects.

Natural-Draft (No Fans) Cooling Towers The A-weighted sound power level of the rim, located at the base, and the discharge, located at the top, of large natural-draft cooling towers is presented in Table 6. Since the low-frequency noise levels of the water flow

Table 4 Overall Sound Power Level of Motor-Driven Pumps

Operating Speed (rpm)	For Motor Ratings under 75 kW	For Motor Ratings above 75 kW
450–900	$68 + 10 \log \text{kW} + 10 \log S$	$79 + 3 \log \text{kW} + 10 \log S$
1000–1500	$70 + 10 \log \text{kW} + 10 \log S$	$81 + 3 \log \text{kW} + 10 \log S$
1600–1800	$75 + 10 \log \text{kW} + 10 \log S$	$86 + 3 \log \text{kW} + 10 \log S$
3000–3600	$72 + 10 \log \text{kW} + 10 \log S$	$83 + 3 \log \text{kW} + 10 \log S$

Table 5 Octave Band and A-Weighted Sound Power Level Adjustments for Directional Effects of Cooling Towers

Source	31.5	63	125	250	500	1000	2000	4000	8000	A

Source	125	250	500	1000	2000	4000	8000	A
Base rim noise	105	104	106	108	110	112	110	117
Discharge noise	100	99	101	103	105	107	105	112

are not significant, sound power levels are not listed for the 31.5- and 63-Hz octave bands.

Packaged Chillers with Compressors The noise from packaged chillers is due primarily to the compressor, not the drive motor, and can be calculated as a function of heat removal (in kW) and the conformal surface area, S (in square metres) at 1 m from the unit (see the Appendix to this chapter for the equation for the conformal surface area). One ton of cooling capacity is equal to 3.52 kW of heat removal.

Packaged Chillers with Reciprocating Compressors⁸ For units with reciprocating compressors, the A-weighted sound power level can be calculated with Eq. (38), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1. The standard error of this equation is estimated to be 5 dB.

$$L_W = 66 + 9 \log \text{ kW} + 10 \log S \quad \text{dB} \quad (38)$$

Packaged Chillers with Centrifugal Compressors⁸ For units with centrifugal compressors, the A-weighted sound power level can be calculated from Eq. (39), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 54 + 11 \log \text{ kW} + 10 \log S \quad \text{dB} \quad (39)$$

The standard error of this equation is estimated to be 4 dB. For larger units with built-up assemblies, use the conformal area of the compressor section only.

Packaged Chillers with Rotary-Screw Compressors² For rotary-screw compressors between 350 and 1000 kW of heat removal operating at approximately 3600 rpm, the A-weighted sound power level is given by Eq. (40), and the unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

$$L_W = 90 + 10 \log S \quad \text{dB} \quad (40)$$

5.2 Construction Equipment: Diesel-Powered, Mobile Equipment¹

The A-weighted sound power level for diesel-powered, mobile equipment such as crawler tractors, dozers, tractor shovels, front-end loaders, backhoes, graders, mobile cranes, and trucks can be calculated using

$$L_W = 94 + 10 \log \text{ kW} \quad \text{dB} \quad (41)$$

where L_W is the A-weighted sound power level and kW is the power rating of the engine. This equation is for turbocharged or naturally aspirated engines with conventional exhaust mufflers. In the typical application, the sound pressure level will average about 4 dB lower than the calculated level since the engine is frequently not operated in the maximum power condition. The unweighted octave band sound power levels can be obtained by subtracting the values shown in Table 1.

6 OIL FIELD EQUIPMENT

Increased governmental noise regulations and concerns about drilling in environmentally sensitive locations have created a need for drilling rig sound pressure level analyses. Representative sound power level data for a standard degasser, drawworks, mud pump, and top drive are presented in Table 7. Some manufacturers offer special noise control options that can provide a reduction of 5 dB to 10 dB from the values provided in Table 7. The sound power for the degasser is typical for a unit rated at 227 m³/h and includes the contribution from the drive motor. The sound power levels for the mud pump and drawworks do not include the drive motors.

7 REGULATIONS

Some governments regulate the sound pressure level or sound power level of different items of machinery. In the United States, no industrial equipment items are regulated at this time.

7.1 European Union Regulations

The European Union published the limits on sound power level as shown in Table 8.⁹ The reported A-weighted sound power level shall be rounded to

Table 7 Octave Band and A-Weighted Sound Power Levels for Oil Field Equipment

^a P_{el} for welding generators: conventional welding current multiplied by the conventional load voltage for the lowest values of the duty factor given by the manufacturer.

P_{el} for power generators: prime power according to ISO 8528-1:1993, point 13.3.2.

^b Indicative figures only. Definitive figures will depend on amendment of the Directive following the report required in Article 20(3). In the absence of any such amendment, the figures for stage I will continue to apply for stage II.

the nearest whole number (less than 0.5, use lower number; greater than or equal to 0.5 use higher number).

7.2 Corporate Requirements

Many corporations require vendors to supply measured acoustical data when providing equipment for new

projects. Often, the A-weighted sound pressure level at 1 m from the equipment outline is limited, such as a maximum sound pressure level of 85 dB. Such a noise specification often results in overestimations of the noise levels in the area of the equipment since the noise levels vary and are actually below the maximum level at many locations around the equipment. Assuming

that the maximum sound pressure level exists at all locations around the equipment may result in sound power level estimates that are higher than actual.

A better specification would be to require the vendor to provide the A-weighted and octave band sound power levels for the equipment. Meeting this specification requires that the vendor measure the sound pressure level at numerous locations around the equipment, and as a result, the sound power level that is calculated from these measurements will more accurately represent the expected sound power in the field.

8 SUMMARY

This chapter has presented procedures for calculating the sound power level of industrial machinery. The reader is encouraged to require vendors to provide sound power level data for their machinery. If all buyers were to require sound power data, then vendors will develop the means to provide it.

APPENDIX: CALCULATION OF CONFORMAL SURFACE AREA

A conformal surface is a hypothetical surface located a distance d from the nearest point on the envelope of the reference box around the equipment. It is different from a rectangular surface because a conformal surface has rounded comers. For large surfaces, the difference in area between a rectangular surface and a conformal surface is typically small ($10 \log S < 1$ dB); however, for small surfaces the difference in areas can be significant ($10 \log S > 2$ dB). The area of a conformal surface can be calculated from

$$S = LW + 2H(L + W) + \pi d[L + W + 2(H + d)] \quad (42)$$

where L is the length, W is the width, and H is the height of the reference box and d is the sound-measurement distance from the reference box.

For example, a noise source 1 m wide, 3 m long, and 2 m high will have a conformal surface area of 50.4 m²

for a 1-m measurement distance. If the energy average A-weighted sound pressure level around the box were 85 dB, the A-weighted sound power level would be 102 dB.

PART VIII

TRANSPORTATION NOISE AND VIBRATION – SOURCES, PREDICTION, AND CONTROL

CHAPTER 83

INTRODUCTION TO TRANSPORTATION NOISE AND VIBRATION SOURCES

Malcolm J. Crocker
Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

The numbers of vehicles and aircraft used in road, rail, and civilian air transportation continues to increase worldwide. Road traffic noise is really a greater problem than aircraft noise in most countries since it affects many more people. The noise of railroad and rapid transit vehicles is also a problem for people living near to rail lines. Noise and vibration sources in road and rail vehicles and aircraft affect not only the occupants but nontravelers as well. Major sources consist of (1) those related to the power plants and (2) those non-power-plant sources generated by the vehicle or aircraft motion. Most rail and rapid transit vehicles have power plant noise and vibration sources that are similar to road vehicles. With rail and rapid transit vehicles, however, tires are mostly replaced with metal wheels, and the wheel-rail interaction becomes a major source of noise and vibration. Brake, gearbox, and transmission noise and vibration are additional problems in road and rail vehicles. In the case of aircraft and helicopters, similar power plant and motion-related sources exist. Some small aircraft are powered by internal combustion engines. Nowadays many general aviation and all medium-size airliners and helicopters are powered by turboprop

power plants. Aircraft propeller and helicopter rotors are major noise sources that are difficult to control. All large civilian aircraft are now powered by jet engines in which the high-speed exhaust and turbomachinery are significant noise sources.

2 NOISE EMISSION IN GENERAL

In cars, trucks, and buses, major power plant noise sources include gasoline and diesel engines, cooling fans, gearboxes and transmissions, and inlet and exhaust systems. Other major sources include tire/road interaction noise and vibration and aerodynamic noise caused by flow over the vehicles.¹ (See Fig. 1.)

Chapters 84 to 93, in Part VIII of this handbook, discuss vehicle and aircraft noise and vibration sources in considerable detail. Although vehicle noise and vibration have been reduced over the years, traffic noise remains a problem because of the continuing increase in the numbers of vehicles. In addition, most evidence suggests that the exterior noise of most new cars, except in first gear, is dominated in normal operation by *rolling noise* (defined here as tire/road interaction noise together with aerodynamic noise), which becomes increasingly important at high speed and exceeds *power train noise* (defined here as engine,

Figure 1 Location of sources of power plant, tire, and wind noise on an automobile.¹

Table 1 Comparison of Rolling and Power Train A-weighted Sound Pressure Levels

Road Speed (km/h)	Vehicle Class	Rolling Noise (dB)	Power Train Noise (dB)	Total Noise (dB)
20	Heavy ^a	61	78	78
	Light	58	64	65
80	Heavy ^a	79	85	86
	Light	76	74	78

^a Heavy vehicles are defined as having an unloaded mass of greater than 1525 kg.

Source: From Nelson.²

air inlet, exhaust, cooling system, and transmission). See Table 1 and the detailed review of vehicle noise by Nelson, who concludes that rolling noise has a negligible effect on the noise produced by heavy vehicles at low speed, but at speeds above 20 km/h for cars and 80 km/h for heavy vehicles, rolling noise contributes significantly to the overall noise level.² At speeds above 60 km/h for cars, rolling noise becomes the dominant noise source.²

Figure 1 of Chapter 86 shows that there is little difference between the exterior noise generated by (1) a modern car at steady speeds (in the top three gears) and (2) the car operating in a coast-by condition at the same steady speeds without the power plant in operation. This suggests that tire noise together with aerodynamic noise are the dominant sources for most normal operations of such a modern car at steady highway speeds. Trucks are dominated by power train noise at low speeds, but at higher speeds above about 80 km/h, exterior truck noise is mostly dominated by tire/road noise and aerodynamic noise. (See Fig. 2, which shows that above 70 to 80 km/h there is little difference between the

exterior noise of the truck whether it is accelerating, cruising at a steady speed, or coasting by with the power plant turned off.¹ Again this suggests that above 70 to 80 km/h this truck's exterior noise is dominated by tire/road noise and aerodynamic noise.) At high speeds above about 130 km/h, vehicle noise starts to become dominated by aerodynamic flow noise.¹ Due to different noise standards for vehicles in different countries and regions, and the condition of the vehicles, the speed at which tire noise starts to dominate may be higher than indicated above. The data here are for modern European vehicles in new condition. For example, in the United States the truck power plants are generally noisier than in Europe. One interesting approach to predict vehicle pass-by noise involves the use of the reciprocity technique.³

Although the latest passenger jets with their bypass turbofan engines are significantly quieter than the first generation of jet airliners, which used pure turbojet engines, the noise of passenger jet aircraft remains a serious problem, particularly near airports. The noisiest pure jet passenger aircraft have been or will soon be retired in most countries. Airport noise, however, is likely to remain a difficult problem since in many countries the frequency of aircraft operations continues to increase and because of the public opposition to noise voiced by some citizens living near airports. This opposition has prevented runway extensions to some airports and the development of some new airports entirely because of environmental concerns.

Additional aspects of vehicle, rail, and aircraft noise sources and control including engines, muffler design, tires, brakes, propellers, gearbox and transmissions, aerodynamic, jet, propeller, and helicopter rotor noise are discussed in Part VIII of this handbook. Part IX is mainly concerned with the interior noise and vibration of road vehicles, off-road vehicles, ships, and aircraft,

Figure 2 Exterior noise of a Volvo F12 truck under different driving conditions.¹

which are experienced by passengers or operators. Noise regulations and limits for vehicle noise that apply to new highway vehicles sold in the United States, Canada, the European Union, Japan, and other countries are described by Chapter 120 and Chapter 71 in Ref. 3. Chapter 120 also describes test procedures used to measure vehicle noise. Part XI of this book deals with community and environmental noise sources, many of which are transportation related. Chapter 121 reviews rail system environmental noise prediction and control methods. Chapter 123 describes ground-borne vibration from roads and rail systems, Chapter 125 discusses aircraft and airport noise, and Chapter 126 describes off-road vehicle noise in the community.

3 INTERNAL COMBUSTION ENGINE NOISE

Although hybrid vehicles, which partially use relatively quiet electric motors, are increasing in use the internal combustion engine (ICE) remains a major source of noise in transportation and industry. ICE intake and exhaust noise can be effectively silenced. (See Chapter 85 in this book.) The noise radiated by vibrating engine surfaces, however, is more difficult to control. In gasoline engines a fuel–air mixture is compressed to about one-eighth to one-tenth of its original volume and ignited by a spark. In diesel engines air is compressed to about one-sixteenth to one-twentieth of its original volume, liquid fuel is injected in the form of a spray, then spontaneous ignition and combustion occurs. Because the rate of cylinder pressure rise is initially more abrupt with a diesel engine than with a gasoline engine, diesel engines tend to be noisier than gasoline engines. The noise of ICE diesel engines has consequently received the most attention from both manufacturers and researchers. The noise of engines can be divided into two main parts: combustion noise and mechanical noise. The combustion noise is caused mostly by the rapid pressure rise created by ignition, and the mechanical noise is caused by a number of mechanisms with perhaps piston slap being one of the most important, particularly in diesel engines. Chapter 84 reviews internal combustion engine noise in detail.

The noise radiated from the engine structure has been found to be almost independent of load, although it is dependent on cylinder volume and even more dependent on engine speed. Measurements of engine noise over a wide range of cylinder capacities have suggested that the A-weighted sound pressure level of engine noise increases by about 17 dB for a 10-fold increase in cylinder capacity.⁴ A-weighted engine noise levels have been found to increase at an even greater rate with speed than with capacity (at least at twice the rate) with about 35 dB for a 10-fold increase in speed. Engine noise can be reduced by attention to details of construction. In particular, stiffer engine structures have been shown to reduce radiated noise. Partial add-on shields and complete enclosures have been demonstrated to reduce the A-weighted noise level of a diesel engine of the order of 3 to 10 dB.

Although engine noise may be separated into two main parts—combustion noise and mechanical noise—there is some interaction between the two noise sources. The mechanical noise may be considered to be the noise produced by an engine that is motored without the burning of fuel. Piston slap occurs as the piston travels up toward top dead center and is one of the mechanical sources that results in engine structural vibration and radiated noise. But piston slap is not strictly an independent mechanical process since the process is affected by the extra forces on the piston generated by the combustion process. The opening and closing of the inlet and exhaust valves, the forces on the bearings caused by the system rotation, and the out of balance of the engine system are other mechanical vibration sources that result in noise. The mechanical forces are repeated each time the crankshaft rotates, and, if the engine is multicylinder, then the number of force repetitions per revolution is multiplied by the number of cylinders. Theoretically, this behavior gives rise to forces at a discrete frequency, f , which is related to R , the number of engine revolutions/minute (rpm), and N , the number of cylinders:

$$f = NR/60 \text{ Hz} \quad (1)$$

Since the mechanical forces are not purely sinusoidal in nature, harmonic distortion occurs. Thus, mechanical forces occur at integer multiples of f given by the frequencies $f_n = nf$, where n is an integer, 1, 2, 3, 4, Assuming that the engine behaves as a linear system, these mechanical forces result in forced vibration and mechanical noise at these discrete frequencies. Combustion noise is likewise partly periodic in nature, and this part is related to the engine rpm because it occurs each time a cylinder fires. This periodic combustion noise frequency, f_p , is different for a two-stroke from a four-stroke engine and is, of course, related to the number of cylinders, N , multiplied by the number of firing strokes each makes per revolution, m .

Some of the low-frequency combustion noise is periodic and coherent from cylinder to cylinder. Some of the combustion noise is not periodic because it is caused by the unsteady burning of the fuel–air mixture. This burning is not exactly the same from cycle to cycle of the engine revolution, and so combustion noise, particularly at the higher frequencies, is random in nature. Research continues on understanding engine noise sources and how the noise energy is transmitted to the exterior and interior of vehicles.^{5,6}

4 INTAKE AND EXHAUST NOISE AND MUFFLER DESIGN

Ducted sources are found in many different mechanical systems. Common ducted-source systems include engines and mufflers (also known as silencers), fans, and air-moving devices (including flow ducts and fluid machines and associated piping). Silencers (also known as mufflers) are used as well on some other machines including compressors, pumps, and air-conditioning systems. In these systems, the source is

the active component and the load is the path, which consists of elements such as mufflers, ducts, and end terminations. The acoustical performance of the system depends on the source–load interactions. System models based on electrical analogies have been found useful in predicting the acoustical performance of systems. Various methods exist for determining the internal impedance of ducted sources. The acoustical performance of a system with a muffler as a path element is usually best described in terms of the muffler insertion loss and the sound pressure radiated from the outlet of the system. Chapter 85 provides a detailed review of the performance of muffler systems. Chapter 14 in the *Handbook of Acoustics* also discusses muffler design and its interaction with the source and load.

There are two main types of mufflers that are fitted to the intake (inlet) and exhaust (outlet) pipes of machinery ductwork. Reactive mufflers function by reflecting sound back to the source and also to some extent by interacting with the source and thereby modifying the source's sound generation. Absorptive silencers on the other hand reduce the sound waves by the use of sound-absorbing material packed into the silencer. The exhaust and intake noise of internal combustion engines is so intense that they need to be “muffled” or “silenced.” Internal combustion engine pressure pulsations are very intense and nonlinear effects should be included. Exhaust gas is very hot and flows rapidly through the exhaust system. The gas stream has a temperature gradient along the exhaust system, and the gas pressure pulsations are of sufficiently high amplitude that they may be regarded almost as shock waves. Some of these conditions violate normal acoustical assumptions. Modeling of an engine exhaust system in the time domain has been attempted by some researchers to account for the nonlinear effects. But such have proved to be challenging. Most modeling techniques have used the transmission matrix approach in the frequency domain and have been found to be sufficiently effective.

The acoustical performance of a ducted-source system depends on the impedances of the source and load and the four-pole parameters of the path. This complete description of the system performance is termed *insertion loss* (IL). The insertion loss is the difference between the sound pressure levels measured at the same reference point (from the termination) without and with the path element, such as a muffler, in place. See Fig. 3a.

Another useful description of the path element is given by the *transmission loss* (TL). The transmission loss is the logarithmic ratio of the incident to transmitted sound powers $S_i I_i / S_t I_t$. See Fig. 3b.

The *noise reduction* (NR) is another descriptor used to measure the effect of the path element and is given by the difference in the measured sound pressure levels upstream and downstream of the path element (such as the muffler), respectively. See Fig. 3c.

The insertion loss is the most useful description for the user since it gives the net performance of the path element (muffler) and includes the interaction

Figure 3 Definitions of muffler performance.

of the source and termination impedances with the muffler element. It can be shown that the insertion loss depends on the source impedance. It is easier to measure insertion loss than to predict it because the characteristics of most sources are not known.

The transmission loss is easier to predict than to measure. The transmission loss is defined so that it depends only on the path geometry and not on the source and termination impedances.

The transmission loss is a very useful quantity for the acoustical design of a muffler system path geometry. However, it is difficult to measure since it requires two transducers to separate the incident and transmitted intensities. The description of the system performance in terms of the noise reduction requires knowledge of both the path element and of the termination.

Figure 3 shows various acoustical performance descriptors used for ducted-source systems. It should be noted that similar system terminology to that described here and shown in Fig. 3 is commonly used for the acoustical performance of enclosures and partition walls in buildings. (See Chapters 58 and 122.) The terminology used for the acoustical performance of barriers is also similar, although the additional descriptor “attenuation” is also introduced for barriers. Note that with barriers the insertion loss descriptor can have a slightly different meaning. (See Chapter 5.)

Chapter 85 contains an extensive review of muffler and silencer modeling and design. Chapter 14 in the *Handbook of Acoustics* also gives a brief review of

modeling of ducted-source systems with emphasis on muffler design. Work on muffler design and modeling continues with approaches varying from completely experimental to mostly theoretical.⁷⁻¹¹

5 TIRE/ROAD NOISE SOURCE MECHANISMS

In most developed and developing countries, vehicle traffic is the main contributor to community noise. Aircraft noise is a lesser problem since it mostly affects small areas of urban communities that are located near to major airports. The substantial increase in road vehicle traffic in Europe, North America, Japan, and other countries suggests that road vehicle traffic will continue to be the dominant source of community noise into the foreseeable future. Legislative pressures brought to bear on vehicle manufacturers, particularly in Europe and Japan, have resulted in lower power unit noise output of modern vehicles. Tire/road interaction noise, caused by the interaction of rolling tires with the road surface, has become the predominant noise source on new passenger cars when operated over a wide range of constant speeds, with the exception of the first gear. When operated at motorway speeds, the situation is similar for heavy trucks and again tire road noise is found to be dominant.

As discussed in Chapter 86, one European study suggests that, for normal traffic flows and vehicle mixes on urban roads, about 60% of traffic noise sound power output is due to tire/road interaction noise. On motorways at high speed this increases to about 80%. Both exterior power plant noise (the noise from the engine, gearbox/transmission, and exhaust system) and tire/road noise are strongly speed dependent. Measurements show that exterior tire/road noise increases logarithmically with speed (about 10 dB for each doubling of speed). Since an increase of 10 dB represents an approximate doubling of subjective loudness, the tire/road noise of a vehicle traveling at 40 km/h sounds about twice as loud as one at 20 km/h; and at 80 km/h, the noise will sound about four times as loud. Studies have shown that there are many possible mechanisms responsible for tire/road interaction noise generation. Although there is general agreement on the mechanisms, there is still some disagreement on their relative importance. The noise generation mechanisms may be grouped into two main types: (1) vibrational (impact and adhesion) and (2) aerodynamic (air displacement).

There are five main methods of measuring tire noise. These methods include (1) close proximity CPX (trailer), (2) cruise-by, (3) statistical pass-by, (4) drum, and (5) sound intensity. Figure 4 shows tire noise being measured by a CPX trailer built at Auburn University.¹²

Figure 5 shows A-weighted sound pressure levels measured with the Auburn CPX trailer. Note that the A-weighted spectrum peaks between 800 to 1000 Hz, and the peak increases slightly in magnitude and frequency as the vehicle speed is increased. Knowledge of tire/road aerodynamic and vibration noise generation mechanisms suggests several approaches, which

Figure 4 View of finished CPX trailer built at Auburn University.¹²

if used properly can be used to help suppress tire/road noise. See Chapter 86.

Perhaps the most hopeful, lower cost, approach to suppress tire/road noise is the use of porous road surface mixes.¹² Porous roads, with up to 20 to 30% or more of air void volume, are being used increasingly in many countries. They can provide A-weighted sound pressure level reductions of up to 5 to 7 dB, drain rain water, and reduce splash-up behind vehicles as well. If the porous road can be designed to have maximum absorption at a frequency between 800 and 1000 Hz, it can be most effective in reducing tire/road interaction noise. Tire/road interaction noise generation and measurement are discussed in detail in Chapter 86. Much research continues into understanding the origins of tire/road noise.¹³⁻¹⁸

6 AERODYNAMIC NOISE SOURCES ON VEHICLES

The interaction of the flow around a vehicle with the vehicle body structure gives rise to sound generation and noise problems both inside and outside the vehicle. Turbulent boundary layer fluctuations on the vehicle exterior can result in sound generation. The pressure fluctuations also cause structural vibration, which in turn results in sound radiated both to the exterior and to the vehicle interior. Abrupt changes in the vehicle geometry result in regions of separated flow that considerably increase the turbulent boundary layer fluctuations. Poorly designed or leaking door seals result in aspiration (venting) of the seals, which allows direct communication of the turbulent boundary layer pressure fluctuations into the vehicle interior. Appendages on a vehicle, such as external rear-view mirrors and radio antennas also create additional turbulence and noise. The body structure vibrations are also increased in intensity by the separated flow regions. Although turbulent flow around vehicles is the main cause of aerodynamic noise, it should be noted that even laminar flow can indirectly induce noise. For example, the flow pressure regions created by laminar flow can distort body panels, such as the hood (bonnet), and incite vibration.

Figure 5 A-weighted sound pressure level one-third octave band tire/road noise measurements made with a CPX trailer built at Auburn University.

At vehicle speeds above about 130 km/h the vehicle flow-generated noise exceeds the tire noise and increases with speed to the sixth power. Because of the complicated turbulent and separated flow interactions with the vehicle body, it is difficult to predict accurately the aerodynamic sound generated by a vehicle and its radiation to the vehicle interior and exterior. Vehicle designers often have to resort to empiricism and/or full-scale vehicle tests in wind tunnels for measurements of vehicle interior and exterior aerodynamic flow generation and interior noise predictions. See Chapter 87 for a detailed discussion on aerodynamic noise generation by vehicles. Statistical energy analysis and computational fluid dynamics have also been utilized to predict interior wind noise on vehicles.¹⁹

7 GEARBOX NOISE AND VIBRATION

Transmissions and gearbox systems are used in cars, trucks, and buses to transmit the mechanical power produced by the engine to the wheels. Similar transmission systems are used in propeller aircraft to transmit power to the propeller(s) from the engine(s) or turbine(s). Transmission gearboxes are also used in some railroad systems and ships. Some modern high-speed rail vehicles, however, are beginning to use motive power systems (electric motors) mounted directly onto the axles of each rail vehicle, resulting in quieter operation and reduced noise problems.

The gearbox can be the source of vibration and radiated noise and should be suitably soft mounted to the vehicle structure, wherever possible. Shaft misalignment problems must be avoided, however, with the mounting system chosen. The principal components of a gearbox are comprised of gear trains, bearings, and transmission shafts.

Unless substantial bearing wear and/or damage have occurred, gear meshing noise and vibration are normally the predominant sources in a gearbox. The vibration and noise produced depend upon gear contact ratios, gear profiles, manufacturing tolerances, load and speed, and gear meshing frequencies. Different gear surface profiles and gear types produce different levels of noise and vibration. In general, smaller gear tolerances result in smoother gear operation but require increased manufacturing costs.

Gearboxes are often fitted with enclosures to reduce noise radiation, since the use of a low-cost gearbox combined with an enclosure may be less expensive than the use of a high-performance gear system and gearbox without an enclosure. Gearbox enclosures, however, can result in reduced accessibility and additional maintenance difficulties. A better approach, where possible, is to try to utilize a lower noise and vibration gear system so that a gearbox enclosure is unnecessary. Chapter 88 deals with gearbox noise and vibration. Chapter 69 specifically addresses gear noise and vibration prediction and control methods.

8 JET ENGINE NOISE GENERATION

The introduction of commercial passenger jet aircraft in the 1950s brought increasing complaints from people living near airports. Not only were the jet engines noisier than corresponding piston engines on airliners, since they were more powerful, but the noise was more disturbing because it had a higher frequency content than piston engines. This was most evident during the 1950s and 1960s when pure turbojet engines were in wide use in civilian jet airliners. Pure jet engines are still in use on some supersonic aircraft and in particular on high-speed military aircraft.

A pure turbojet engine takes in air through the inlet, adds fuel, which is then burnt, resulting in an expanded gas flow and an accelerated very high speed exhaust jet flow. The whole compression, combustion, and expansion process results in the thrust produced by the engine. The kinetic energy in the exhaust is nonrecoverable and can be considered as lost energy. Since the 1970s, turbofan (or bypass) jet engines have come into increasing use on commercial passenger airliners. Turbofan engines have a large compressor fan at the front of the engine, almost like a ducted propeller. A large fraction of the air, after passing through the fan stage, bypasses the rest of the engine and then is mixed with the high-speed jet exhaust before leaving the engine tail pipe. This results in an engine that has a much lower exhaust velocity than for the case of a pure jet engine. The thrust can still be maintained if a larger amount of air is processed through the turbofan engine than with the pure turbojet engine (in which no air is bypassed around the combustion chamber and turbine engine components). The efficiency of the turbofan engine is greater than that of a pure turbojet engine, however, since less kinetic energy is lost in the exhaust jet flow.

A simplified calculation clearly shows the advantage of a turbofan engine over a turbojet engine. For instance, if a turbofan engine processes twice as much air as a turbojet engine, but only accelerates the air half as much, the kinetic energy lost will be reduced by half ($1 - 2 \times \frac{1}{4}$), while the engine thrust is maintained. If the engine processes four times as much air, but accelerates the air only one quarter as much, the kinetic energy lost will be reduced by three quarters ($1 - 4 \times \frac{1}{16}$) and the engine thrust is still maintained. In each successive case described, the engine will become more efficient as the lost kinetic energy is reduced. Fortunately, as originally shown by Lighthill, there is an even more dramatic reduction in the sound power produced since in a jet exhaust flow the sound power produced is proportional to the exhaust velocity to the eighth power.²⁰⁻²² A halving in exhaust velocity then, theoretically, can give a reduction of 2^8 in exhaust sound power and mean square sound pressure, and in sound power level and sound pressure level of about $80 \log_{10} (2)$ or about 24 dB. But, of course, if the mass flow is twice as much, then the reduction in sound power and in the mean square pressure is about 2^7 , or a reduction in sound power level and sound pressure level of about 21 dB.

The major noise sources for a modern turbofan engine are discussed in detail in Chapter 89. Chapter 9 is devoted to a review of the theory of aerodynamic noise and in particular jet noise generation. The relative sound pressure levels generated by each engine component depend on the engine mechanical design and power setting. During takeoff, the fan and jet noise are both important sources with the exhaust noise usually dominant. During landing approach, the fan noise usually dominates since the engine power setting and thus jet exhaust velocity are reduced. Noise from other components such as the compressor, combustion chamber, and turbine is generally less than that from the fan and the jet. The noise radiated from the inlet includes contributions from both the fan and compressor but is primarily dominated by the fan. Downstream radiated noise is dominated by the fan and jet, but there can also be significant contributions from the combustor and turbine, whose contributions are very much dependent on each engine design.

Reliable jet engine noise prediction methods are difficult to develop since they depend on accurate prediction of the unsteady flow field in and around the engine. Methods for reducing jet engine noise include modifying the unsteady flow field, redirecting the sound generated, absorbing the sound using acoustical treatments, and/or combinations of all three. See Chapter 89 for a fuller discussion.

9 AIRCRAFT PROPELLER NOISE

As described in Chapter 90, propellers are used on small general aviation aircraft as well as small to medium size passenger airliners. (see Fig. 6.) In small general aviation aircraft, propellers operate with a fixed-blade pitch. In larger general aviation and commuter aircraft, they operate with adjustable pitch to improve aircraft takeoff and flight performance. Smaller aircraft have two-blade propellers while larger aircraft have three or more blades. The propeller operation gives rise to blade thrust and drag forces.

For a single propeller, tones are generated, which are harmonics of the blade passage frequency (BPF). This phenomenon occurs even for the case of tones generated by blade-turbulence interaction, which is caused by turbulent eddies in the airflow approaching the propeller. The BPF is the product of the shaft frequency and the blade number.

Theoretically, the BPF is a discrete frequency, f_{BPF} , which is related to the number of blades, N , and the engine rpm, R , and is given by $f_{BPF} = NR/60$ Hz. Since the thrust and drag forces are not purely sinusoidal in nature, harmonic distortion occurs as in the case of the noise generated by fans, diesel engines, pumps, compressors, and the like. Thus, blade passing harmonic tones occur at frequencies f_{BPFn} given by $f_{BPFn} = nNR/60$ Hz, where n is an integer, 1, 2, 3, 4, ...

Prediction of propeller noise is complicated. Accurate noise predictions require methods that include the influence of the flow field in which the propeller operates. Predictions may be made both in the time domain and the frequency domain. Noise reduction approaches

Figure 6 Noise levels and spectra of general aviation aircraft.²³

are normally based both on experimental tests and theoretical predictions. See Chapter 90 for a more complete discussion.

The spectrum of the propeller noise has both discrete and continuous components. The discrete frequency components are called tones. The continuous

component of the spectrum is called broadband noise. There are three main kinds of propeller noise sources. These are (1) thickness (monopole-like), (2) loading (dipole-like), and (3) nonlinear (quadrupole-like) noise sources. All three of these source types can be steady or unsteady in nature. The loading dipole axis exists

along the local normal to the propeller plane surface. For the first few harmonics of a low-speed propeller, the simple Gutin formula² gives the noise level in terms of the net thrust and torque. Unsteady sources can be further classified as periodic, aperiodic, or random. Steady and periodic sources produce tonal noise while random sources produce broadband noise.

Quadrupole sources are normally only important when the flow over the propeller airfoil is transonic or supersonic. Quadrupole sources are not important noise generators for conventional propellers, but they can be important in the generation of the noise of highly loaded high-speed propellers such as propfans. (See Chapters 9 and 10 for more detailed discussions on aerodynamic noise and nonlinear acoustics.)

10 HELICOPTER ROTOR NOISE

The generation of helicopter rotor noise is very complicated. Chapter 91 provides an in-depth discussion about its causes. Sources of helicopter noise include (1) main rotor, (2) tail rotor, (3) the engines, and (4) the drive train components. The dominant noise contributors are the main rotor and the tail rotor. Engine noise is normally less important, although for large helicopters engine noise can be dominant at take-off. Rotor noise including main rotor and tail rotor noise can be classified as (1) discrete-frequency rotational noise, (2) broadband noise, and/or (3) impulsive noise (also of discrete-frequency character).

Helicopter rotor noise is comprised of *thickness noise* (the noise generated from the periodic volume displacement of the rotating blades) and *loading noise* (caused by the rotating lift and drag forces). Thickness noise is more important in the low-frequency range of the rotor-noise spectrum (at the blade passage frequency and first few harmonics). It also contains mid- and high-frequency components since it is of an impulsive nature). At low rotational speeds and for low blade loading, the thickness noise line spectrum can be exceeded by the *broadband noise* components. Broadband noise is a result of turbulent inflow conditions, blade/wake interferences, and blade self-noise ("airframe noise").

Of great importance are *impulsive-type noise sources*, resulting in the familiar "bang, bang, bang" sound. There are two main kinds: high-speed (HS) impulsive noise and blade-vortex interaction (BVI) impulsive noise. Tail rotor noise has similar characteristics to the main rotor noise. The flow around the tail rotor is the sum of the interacting flows generated by the wakes of the main rotor, the fuselage, the rotor hub, as well as the engine exhaust and empennage flows in addition to its own wake. For most helicopters, the tail rotor noise dominates at moderate speed straight flight conditions and during climb. Practical *rotor noise reduction measures* include passive reduction of high-speed impulsive noise, reduction of tail rotor noise, and active reduction of blade-vortex interaction. (See Chapter 91 for a more detailed discussion of helicopter rotor noise.) Lowson has provided an in-depth review on helicopter noise.²⁴

11 BRAKE NOISE PREDICTION AND CONTROL

Brake noise has been recognized as a problem since the mid-1930s. Research was initially conducted on drum brakes, but recent work has concentrated on disk brakes since they are now widely used on cars and trucks. The disk is bolted to the wheel and axle and thus rotates at the same speed as the wheel. The brake caliper does not rotate and is fixed to the vehicle. Hydraulic oil pressure forces the brake pads onto the disk, thus applying braking forces that reduce the speed of the vehicle.

As is discussed in Chapter 92, from a dynamics point of view a braking system can be represented as two dynamic systems connected by a friction interface. The normal force between the two systems results from the hydraulic pressure and is related to the friction force. The combination of the friction interface and the dynamic systems makes it difficult to understand and reduce brake noise. Brake noise usually involves a dynamic instability of the braking system.

There are three overlapping "stability" parameters of (1) friction, (2) pressure, and (3) temperature. If the brake operates in the unstable area, changes in the parameters have little or no effect, and the brake is likely to generate noise. Such conditions may be caused by excessively low or high temperatures, which cause changes in the characteristics of the friction material. The "stable" area may be regarded to represent a well-designed brake in which the system only moves into the "unstable" region when extreme changes in the system parameters occur. Brake noise and vibration phenomena can be placed into three main categories: (1) judder, (2) groan, and (3) squeal.

Judder occurs at a frequency less than about 10 Hz and is related to the wheel rotation rpm or a multiple of it. It is a *forced* vibration caused by nonuniformity of the disk, and the vibration is of such a low frequency that it is normally sensed rather than heard. There are two types of judder: cold and hot judder. Cold judder is commonly caused by the brake pad rubbing on the disk during periods when the brakes are not applied. Hot judder is associated with braking at high speeds or excessive braking when large amounts of heat can be generated causing transient thermal deformations of the disk.

Groan occurs at a frequency of about 100 Hz. It usually happens at low speed and is the most common unstable brake vibration phenomenon. It is particularly noticeable in cars and/or heavy trucks coming to a stop or moving along slowly and then gently braking. It is thought to be caused by the stick-slip behavior of the brake pads on the disk surface and because the friction coefficient varies with brake pad velocity.

Squeal normally occurs above 1 kHz. Brake squeal is an unstable vibration caused by a geometric instability. It can be divided into two main categories: (1) low-frequency squeal (1 to 4 kHz), diametrical nodal spacing in the disk, and (2) high-frequency squeal (>4 kHz). See Chapter 92 for a more detailed discussion of brake noise. References 25 to 30 describe recent research on brake noise.

12 WHEEL–RAIL INTERACTION NOISE

Noise produced by wheel–rail interaction continues to be of concern in railway operations. Many studies have been conducted on wheel–rail interaction noise. Most of the studies have involved various measurement approaches.^{31–40} Main wheel–rail sources include (1) rolling noise, which is caused by small-scale vertical profile irregularities (roughness) of wheel and rail, (2) impact noise caused by discrete discontinuities of the profile such as wheel flats, rail joints, or welds, and (3) squeal noise that occurs in curves. In each case, the noise is produced by vibrations of the wheels and track. The dynamic properties of the wheel and track have an affect on the sound radiation. Control measures for rolling noise include reduced surface roughness, wheel shape optimization and added wheel passive damping treatments, increased rail support stiffness, or use of local wheel–rail shielding. The use of trackside noise barriers is becoming common for railways. Barriers are discussed in Chapter 58. For squeal noise, mitigation measures include friction control by lubrication or friction modifiers. Chapter 93 discusses causes of wheel–rail noise and methods for its control.

A train running on straight unjointed track produces rolling noise. This is a broadband, random noise radiated by wheel and track vibration over the range of about 100 to 5000 Hz. The overall radiated sound pressure level increases at about 9 dB per doubling of train speed. This represents almost a doubling of subjective loudness for a doubling of speed. Rolling noise is induced by small vertical profile irregularities of the wheel and rail running surfaces. This is often referred to as roughness, although the wavelength range is between about 5 and 250 mm, which is greater than the range normally considered for microroughness. Wheel and rail roughness may be considered incoherent and their noise spectra simply added. The roughness causes a relative displacement between the wheel and rail and makes the wheel and rail vibrate and radiate noise. See Chapter 93 for a complete discussion on wheel–rail interaction noise.

CHAPTER 84

INTERNAL COMBUSTION ENGINE NOISE PREDICTION AND CONTROL – DIESEL AND GASOLINE ENGINES

Thomas E. Reinhart
Engine Design Section
Southwest Research Institute
San Antonio, Texas

1 INTRODUCTION

Internal combustion engines designed to operate on gasoline or diesel fuel (or their substitutes) have different combustion systems that lead to significantly different noise characteristics. Gasoline engines use spark ignition to control the combustion process, while diesel cycle engines use compression ignition. The forces generated inside internal combustion engines cause vibration of the engine structure, leading to radiated noise. Important forcing functions include cylinder pressure, piston slap, and impact excitations, which are generated as clearances open and close. Engines with timing gears have backlash rattle, and most timing drives experience meshing frequency forces. Engine accessories often produce tonal noise that contributes to the overall engine noise. Which forcing function dominates the noise of an engine depends on the engine design, combustion system, and operating condition. The relative importance of different forcing functions varies as a function of speed and load.

The noise of internal combustion engines can be predicted using information about the size, speed, and combustion process. Noise levels of all engine types increase with bore size and operating speed. However, a number of techniques are available to control engine noise, so all engines of a given size, speed, and combustion process will not have identical noise levels. Noise control techniques include changes to the combustion process, to the engine structure, and to internal and external components such as pistons and valve covers. Engine or vehicle-mounted enclosures are often used to limit noise radiation.

2 BASIC CHARACTERISTICS OF DIESEL AND GASOLINE ENGINES

Many books have been devoted to the design of diesel and gasoline engines. In this chapter, we will only consider characteristics relevant to noise generation. Diesel and gasoline engines share many similarities. They all have pistons, cylinders, connecting rods, crankshafts, blocks, heads, valve or porting systems, and so forth. These components often look similar between gasoline and diesel engines, but diesel components tend to be designed to withstand higher loads. The primary distinction between gasoline and

diesel engines lies in the combustion process and how fuel is delivered to and burnt in the cylinder.

Gasoline engines, along with many alternate fueled engines, use the Otto cycle, with spark ignition. Spark ignition (SI) engines create a mixture of air and fuel in the cylinder and ignite it with a spark plug. The air–fuel mixture starts burning at the spark plug, and the flame front propagates across the cylinder until all the fuel has been burned. It is critical that the unburned air and fuel not spontaneously ignite. This autoignition in an SI engine is called *knock*. It causes a step increase in cylinder pressure, which produces the characteristic “pinging” or “knocking” noise. Significant levels of knock are highly destructive to an SI engine since the engine components are not designed to withstand the huge forces and high temperatures created by knock.

Compression ratios and peak cylinder pressures are limited in SI engines by the need to avoid knock. The fuel is also developed to help avoid knock. The familiar octane ratings are a measure of the ability of fuel to resist autoignition. A higher octane rating allows the engine designer to use higher compression ratios and cylinder pressures without fear of knock, which can improve both power and efficiency.¹

Diesel engines are also known as compression ignition (CI) engines. They rely precisely on the type of combustion that SI engines try to avoid: autoignition. In a diesel engine, the air–fuel mixture is compressed until ignition occurs spontaneously. As a result, diesel engines tend to have much higher compression ratios, peak cylinder pressures, and rates of pressure rise than SI engines. Diesel engines are designed to withstand the higher forces produced by the compression ignition process. Diesel fuel is designed to promote autoignition, and this characteristic is measured and reported as the cetane value. A fuel with higher cetane will ignite more easily.

The different combustion methods used in SI and CI engines go a long way toward explaining the noise and vibration disadvantages that diesel engines face compared to gasoline engines. The forces from cylinder pressure and the high-frequency excitation from rates of pressure rise are much higher in CI engines. Rapid pressure rise involves significant high-frequency energy content, which manifests itself in the typical diesel knocking sound. Heavier moving parts, required to survive the higher forces in a diesel,

also contribute to the higher noise and vibration levels of diesels. The high compression ratios of diesels cause large fluctuations of crankshaft speed (torsional vibration). Torsional vibration produces torque reactions that are transmitted to the engine mounts, making it more difficult to achieve good vibration isolation with diesel engines.

3 DIRECT INJECTION VERSUS INDIRECT INJECTION

Many small SI engines still use carburetion to mix air and fuel before introducing it into the cylinder for combustion, but most larger SI and all CI engines use some form of fuel injection. However, SI and CI injection systems are quite different. CI (diesel) engines typically inject fuel at very high pressures. On modern diesels, injection pressures of 1400 to over 2000 bar are common. Modern gasoline port injection systems, on the other hand, work at pressures of 3 to 6 bar. Even direct injection gasoline systems generally use pressures of under 100 bar. Creating and controlling the extremely high pressures used in diesel fuel systems makes the systems themselves potentially significant noise sources.

All diesel engines use some form of fuel injection. Indirect injection (IDI) used to be very common in small and medium size diesels, while larger engines tended to use direct injection (DI). Recently, the trend is toward direct injection for all but the smallest diesel engines. An important advantage of IDI is lower combustion noise. This is because the effect of forcing air and fuel through the passage between the prechamber and main cylinder reduces rates of pressure rise in the cylinder. However, the prechamber produces pumping losses that have the effect of reducing fuel economy by 10 to 15%. The better fuel economy of DI engines has driven the trend toward DI in smaller diesels.^{2,3}

4 PREDICTING NOISE FROM ENGINE SIZE, SPEED, AND COMBUSTION SYSTEM

Engine noise is widely known to vary with engine size, speed, and combustion system. The empirical relationships among these have been described in several published works. For example, in 1970, Anderton et al. evaluated a large sample of diesel engines and concluded that sound pressure level was proportional to speed to the third power for naturally aspirated engines and speed to the fourth power for turbocharged engines. For both engine types, noise was proportional to bore to the fifth power.⁴ In the mid-1970s, two papers were published that included empirical equations to predict the overall average 1-m noise level for several types of engines.^{5,6} These equations also covered high-speed IDI diesels and gasoline engines.

In 2004 a new paper was published by one of the original authors of Ref. 5 providing updated empirical equations based on more recent engine noise tests.⁷ The average A-weighted sound pressure level in

decibels, measured 1m from the engine, for an engine running at full load is given by:

$$30 \log(N) + 50 \log(B) - 106$$

(for NA DI diesels) (1)

$$25 \log(N) + 50 \log(B) - 86$$

(for turbocharged diesels) (2)

$$36 \log(N) + 50 \log(B) - 133$$

(for IDI diesels) (3)

$$50 \log(N) + 30 \log(B) + 40 \log(S) - 223.5$$

(for gasoline) (4)

where N = speed in rpm, B = bore in mm, and S = stroke in mm, NA refers to natural aspiration, and base 10 logarithms are used.

A recent study of heavy-duty (HD) diesel engines failed to support the empirical equations from the above references, or indeed any clean relationship between noise, speed, and engine size.⁸ This study found that changes in emissions regulations have caused a new forcing function, gear train rattle, to become the dominant noise forcing function in many HD diesel engines. For certain HD diesel engines, gear train design parameters proved to be a much more reliable indicator of noise than bore and speed.⁸

One interesting observation is that most engines make about the same amount of noise at their maximum speed and load. As Fig. 1⁹ shows, from small gasoline car engines to large, heavy-duty truck diesels, average 1-m A-weighted sound pressure levels at rated speed and load are often in the 95 dB to 105 dB range. Larger engines tend to have a lower maximum speed than small engines, and inherently loud diesel engines have a lower maximum speed than quieter gasoline engines. The net result is that many engines have similar noise levels at maximum speed and load, although noise levels compared at a given speed can vary by up to 30 dB.

Figure 2 shows typical sound pressure spectra for two engines operating at maximum speed and load. One engine is a small four-cylinder gasoline car engine, while the other is a heavy-duty truck V-8 turbocharged DI diesel. The overall noise levels for the two engines are not very different, but some differences in the sound pressure spectra can be observed. There is no clear pattern below 1250 Hz. In one band, the diesel is higher, while the gasoline engine is higher in the next band. From 1250 to 2500 Hz, the two engines are nearly identical. The diesel is louder in frequencies above 2500 Hz. This high-frequency content is due to combustion, gear train, and fuel system excitations and is responsible for the relatively poor sound quality of the diesel. Even though overall levels at maximum speed and load are similar, the gasoline engine is about 20 dB quieter than the diesel at idle.¹⁰

Figure 1 Typical full-load sound pressure levels of engines, measured 1 m from the engine.⁹

Figure 2 Sound pressure level spectra of a small four-cylinder gasoline car engine and a V-8 turbocharged DI heavy-duty diesel truck engine at maximum speed and load.¹⁰

5 NOISE GENERATION MODEL

Figure 3 shows a model in block diagram form for engine noise generation that applies to both gasoline and diesel engines. Large forces are generated inside an engine, and these forces are applied to the internal structure. The applied forces are typically divided into two categories: combustion forces (cylinder pressure) and mechanical forces (all other forcing functions).

These forces produce vibration in the structure, and the vibration is transmitted to external components that can radiate sound. The design of the structure determines how much vibration is transmitted to the external components for a given amount of force input. The design of the external components determines how much of the vibration transmitted through the structure is transformed into radiated noise. There are

Figure 3 Block diagram model of engine noise generation.

opportunities for the designer to intervene at each stage of the noise generation process. Design changes can be made to reduce the input forces, or to make the structure less responsive to given input forces, or to make the external components radiate less noise for a given structural vibration input.

6 COMBUSTION NOISE

Combustion can be a dominant noise source in both SI and CI engines. The distinction between combustion and mechanical noise seems clear, but in practice separating the two can be difficult. Combustion excites the engine structure through rapid changes in cylinder pressure. The direct excitation of the engine structure (piston and cylinder head) by cylinder pressure is normally referred to as *combustion noise*. However, cylinder pressure is directly or indirectly responsible for many mechanical noises in the engine. For example, cylinder pressure can drive bearing impacts and piston slap. Cylinder pressure also leads to crankshaft speed fluctuations, which can cause gear train rattle or timing chain slap. If changes are made to the engine that result in a reduction of peak cylinder pressure or in the rate of pressure rise, it can be difficult to determine whether the observed noise reduction is because of a reduction in direct combustion noise or because of a change in some mechanical noise source(s), which are driven by cylinder pressure.⁸

Figure 4 shows a typical cylinder pressure trace for a diesel engine, while Fig. 5 shows typical cylinder pressure frequency spectra for gasoline and diesel engines. The diesel cylinder pressure trace in Fig. 4 is similar to that of a gasoline engine experiencing knock. In a diesel, cylinder pressure increases smoothly up past the beginning of injection. Once injection begins, the fuel evaporates, heats up, and finally reaches the conditions where autoignition is possible. When autoignition occurs, virtually all the fuel injected in the cylinder up to the point of ignition burns explosively, causing a very rapid rise in cylinder pressure. This explosive onset of combustion is often referred to as *premixed combustion*.

The step increase in cylinder pressure produced by premixed combustion causes the broadband increase in cylinder pressure spectrum of the diesel, shown in Fig. 5. Since the combustion is not perfectly symmetric, the pressure then oscillates at the natural frequencies of the air volume trapped in the cylinder, as can be seen in Fig. 4 at the point just after the cylinder pressure spike. Often, more than one

Figure 4 Typical cylinder pressure trace of a diesel engine at low boost pressure.

resonance frequency can be seen in a spectrum of cylinder pressure because the first few modes of the gas trapped in the cylinder can all be excited (see the high-frequency peaks in Fig. 5).

The frequency content of the cylinder pressure is crucial to determining the level of combustion noise. If the cylinder pressure trace is smooth, there will be very high amplitudes of low-frequency excitation to the engine structure but little high-frequency content. If premixed combustion (or knock in an SI engine) causes a step increase in cylinder pressure, there will be much more high-frequency excitation of the engine structure. The frequency spectrum of the cylinder pressure trace is therefore a useful predictor of combustion noise. In fact, combustion noise meters were developed in the 1980s to take advantage of this effect. The transfer function between the cylinder pressure spectrum and the engine-radiated noise spectrum was determined for a number of engines, averaged, and built into a meter.¹¹ The combustion noise meter allows performance development engineers to predict the effect of combustion system changes on overall engine noise. The predictions of a combustion noise meter are valid only as long as the transfer function used by the meter is a reasonably accurate representation of the engine being tested.

7 REDUCING COMBUSTION NOISE

In all engines, combustion noise is controlled by the rate of heat release (combustion), which determines the rate of rise in cylinder pressure. In gasoline engines, heat release is controlled by factors such as:

Figure 5 Typical cylinder pressure level spectra of diesel and gasoline engines. Gasoline engines have lower levels at low frequency because of lower peak cylinder pressure. The peaks in the high-frequency spectra of diesels reflect combustion chamber resonances excited by premixed combustion.

- Ignition (spark) timing
- Spark plug location
- Number of spark plugs
- Swirl and tumble of the air–fuel mixture

Retarding ignition toward top dead center (TDC) reduces combustion noise significantly, at a cost in performance. A centrally located spark plug will produce more rapid combustion than one located near the side of the combustion chamber. Two spark plugs fired together speed combustion compared to a single plug. Higher swirl and tumble of the air–fuel mixture speeds combustion. Swirl and tumble are controlled by a number of factors, including port design, valve lift, valve timing, and combustion chamber shape (squish).

In diesel engines, the rate of heat release is also controlled by a number of factors, including:

- Injection timing
- Boost pressure
- Compression ratio
- Intake manifold temperature
- Injection characteristics
- Fuel cetane

Retarding injection timing reduces combustion noise, unless the start of combustion is pushed after TDC. Increasing boost pressure causes the fuel to evaporate and mix more quickly, shortening the ignition delay and thus reducing combustion noise. In fact, at boost pressures above about 0.7 bar, combustion noise often becomes insignificant. Higher compression ratios and higher intake manifold temperatures also have the effect of shortening ignition delay and reducing combustion noise. Injection characteristics such as pilot injection and rate shaping can have a dramatic effect on combustion noise, by reducing the amount of fuel

injected during the ignition delay. In some DI diesel engines, the use of pilot injection can reduce overall noise under low-speed and light-load conditions by 5 dB or more, with a dramatic improvement in sound quality. Higher cetane fuel reduces ignition delay. European diesel fuel has typical cetane values of 50 to 52, compared to American fuel at about 42. In engines where combustion noise controls the overall noise level, the use of higher cetane fuel will reduce overall noise by 1 to 2 dB and improve sound quality.

8 CONNECTIONS BETWEEN COMBUSTION NOISE, PERFORMANCE, EMISSIONS, AND FUEL ECONOMY

As with many systems, the most straightforward ways of reducing noise also tend to degrade the system performance. There is considerable competition between competing priorities in engine development, and combustion noise is a typical example.

With spark ignition engines, many efforts to improve emissions and fuel economy result in more rapid combustion. This, in turn, leads to higher rates of cylinder pressure rise and more high-frequency content in the cylinder pressure spectrum. For example, features such as high turbulence in the combustion chamber or twin spark plugs are ways of improving emissions or performance at the expense of combustion noise. Noise and vibration compromises frequently need to be made when developing a new combustion system.

In compression ignition engines, the situation is even more difficult. The compression ignition combustion method at the heart of the diesel by its nature causes substantial combustion noise. Historically, it has been difficult to significantly reduce combustion noise without large performance or emissions penalties. However, new fuel systems and electronic controls have opened the door to much improved trade-offs in recent years. The ability to provide several

separate injection events with precise control of quantity and timing has allowed much better trade-offs between noise, emissions, and performance. Many modern diesels combine high power density, good fuel economy, relatively low emissions, and low combustion noise in a way that was simply not possible 10 to 15 years ago, and there appears to be considerable scope for further improvement in the future.

9 MECHANICAL NOISE SOURCES

Many mechanical noises in an engine are caused by the clearances that must exist to allow the engine to function. Most clearance-driven noise sources produce broadband, impact-like inputs to the engine structure. For example, piston slap is caused by the piston moving laterally or rocking in the cylinder and impacting against the cylinder wall. Connecting rod and crankshaft bearings produce impact excitations as the components move through the available clearance. Valve train components produce impacts as they move through their clearances and as valves close against their seats. Engines with gear-driven components may suffer gear rattle impacts, driven by the cyclic torques applied to some of the components such as the crankshaft, camshaft, and fuel system.

Other mechanical noise sources in an engine are periodic in nature. An oil pump will produce pressure fluctuations at a frequency determined by the number of gear teeth or lobes in the pump, combined with the pump's drive ratio. Gear and chain drives can produce pure tone noise at the tooth or sprocket meshing frequency. Alternators, power steering pumps, and other engine-mounted accessories can produce significant pure-tone noise.

Identifying pure-tone engine noise sources is often relatively straightforward. The frequency of the measured noise at a certain speed can be compared to calculations of potential source frequencies. Identifying the sources of impact noise can be much more difficult. By nature, impact noise is broadband, so frequency analysis is of limited help. Measuring when the impacts occur as a function of crank angle may provide guidance. Introducing modified parts designed to magnify or eliminate particular clearances can also be used to identify the source of impact excitations. For example, Teflon-padded pistons can be used to determine the amount of noise generated by piston slap.

10 REDUCING MECHANICAL NOISE

There is extensive literature that describes efforts to reduce mechanical noise. Piston slap has perhaps received the most attention. Analytical models have been created to model and predict the relative motion between the piston and bore.^{12–14} Piston slap modeling software is sold by companies such as AVL, FEV, and Ricardo. These models can be modified to explore a wide range of potential design alternatives, such as changes in clearance, piston pin location, or piston mass. However, it must be noted that piston slap is a complex and sometimes nonlinear phenomenon with many variables, so a model that can accurately simulate it must also be complex.

Piston slap reduction efforts have focused on the effects of these and other variables:

- Piston skirt profile, both top to bottom and around the circumference
- Bore distortion
- Piston pin offset
- Piston coatings to reduce friction or to allow a tighter fit
- Piston inserts to control thermal expansion
- Piston skirt stiffness

A tight-fitting piston provides less opportunity for slap. Reducing bore distortion, controlling thermal expansion, modifying the skirt profile, and using coatings are all means of allowing a tighter fit without risking scuffing and engine seizure. Piston pin offsets have been demonstrated to help reduce piston slap noise by changing the way pistons rotate while crossing the bore. Getting the relatively soft and light piston skirt to impact on the cylinder wall first provides less excitation than having the piston top land impact first.

Both experimental and analytical work has been done on the effects of crankshaft and connecting rod bearing clearances and oil film characteristics.^{15,16} The analytical work is made complex by the nonlinear nature of oil film behavior. To model crankshaft, oil film, and bearing behavior, commercial software packages are available from companies such as AVL and Ricardo.

Valve train noise is a significant problem in many engines. Hydraulic valve lifters are often used to eliminate the lash in valve trains and thus reduce noise. Careful tuning of cam profiles to eliminate force spikes in the valve train can reduce noise. Minimizing “jerk,” the derivative of acceleration, is an important tool for reducing valve train noise. Several software packages are available that can be used to model valve train dynamics.

Noise reduction of accessories such as oil pumps, power steering pumps, alternators, air-conditioning compressors, and the like is often important. It is also important that accessories be mounted to the engine in a way that avoids mounting bracket resonances being excited by important forcing functions such as engine firing frequency. Designers often try to design accessory mounting brackets to achieve a mounted natural frequency above firing frequency at maximum speed.

11 REDUCING STRUCTURAL RESPONSE TO FORCE INPUTS

The engine structure should be designed to produce a minimum of vibration response to known or suspected force inputs. High stiffness is normally used to improve the forced response of the engine structure. An ideal structure would incorporate impedance mismatches to minimize the response of the structure. Impedance mismatches are step changes in stiffness. For example, an engine block could be designed to be very stiff at the location where crankshaft forces

are transmitted through the main bearings, but soft between the main bearing area and the oil pan flange, and stiff again at the oil pan flange. These transitions in stiffness would make it difficult for forces applied at the main bearings to produce vibration at the oil pan flange.

In practice, most structural parts of engines are castings or forgings, which makes it very difficult to achieve large changes in stiffness. Therefore, while efforts to reduce the structural response can provide significant benefits, there are limits to the improvements that can be achieved within weight and cost limitations. In practice, the noise reductions achieved by optimizing the structure are often modest, and they can be easily outweighed by changes in forcing functions.

Finite element models are frequently used to help design engine structures in a way that minimizes vibration response to forces applied.¹⁷ Measured or calculated forces are applied to a model of the structure, and the response at important locations is calculated. The models can be used to test a variety of design alternatives much more quickly than can be done by building and testing hardware.

Smaller engines often radiate a significant amount of noise from the first few modes of the engine or power train, such as the first bending and torsional vibration modes. Finite element models can be used to ensure that important modes occur above the frequency range of primary excitations such as engine firing. Larger engines often radiate significant energy from local modes of the structure, such as panel modes of the engine block. Again, modeling can be used to cost effectively modify the structure to push these modes up beyond the range of strong forcing functions.

12 NOISE RADIATION FROM EXTERIOR SURFACES

Exterior surfaces include both covers, such as the oil pan and valve covers, and structural portions of the engine, such as the block and cylinder heads. A number of options are available to reduce radiated noise, such as stiffening of exterior surfaces, reducing the stiffness of surfaces, adding damping treatments, or isolating the connection between the structure and covers.

Most engineers intuitively believe that adding stiffness is bound to be a good way to reduce noise. Unfortunately, this is not always the case. Adding stiffness can sometimes cause a substantial noise *increase*. A number of factors must be understood in order to determine whether stiffening is a good idea.

Consider the oil pan of a heavy-duty diesel engine as an example. In many engines, the oil pan is not a structural member, allowing the designer a great deal of freedom in choosing the stiffness of the pan. One consideration is the frequency content of the vibration at the pan rail of the engine block, which forms the input excitation to the oil pan. If the pan rail vibration is primarily at low frequencies, it makes sense to stiffen the pan so that the first resonance frequency is above the primary input vibration frequencies. On the other hand, if there is a lot of high-frequency

input, stiffening the pan will have less, or even a negative, benefit. The second consideration is A-weighting. In many cases, noise targets are set using A-weighted levels, which discounts low-frequency noise and emphasizes noise in the 1- to 4- kHz range. Increasing the stiffness of the pan pushes resonances up into the range where A-weighted levels will be higher.

The final design consideration is radiation efficiency. Radiation efficiency is a measure of how much of the vibration in a surface is translated into radiated sound. If the wavelength of sound in air is long compared to the mode shape of the oil pan, radiation efficiency is low. Radiation efficiency peaks when the wavelength of sound in air matches the wavelength of the pan's mode shape, and this is called the critical frequency. Radiation efficiency remains high when the wavelength of sound in air is shorter than the mode shape's wavelength. Reducing radiation efficiency of a given mode shape requires lowering the natural frequency of the mode. Another way to look at radiation efficiency is to say that for a given frequency, the more complex mode shapes will generally have lower radiation efficiency. Closed-form solutions are available to calculate the radiation efficiency of simple geometries such as flat plates, but the complex shapes of real engine components usually require numerical solutions.¹⁸

Figure 6 shows a comparison of mean square surface velocity for two different oil pans on a heavy-duty diesel engine. The cast-aluminum oil pan is much stiffer than the stamped steel oil pan, and its natural frequencies are higher. As a result, the aluminum pan enjoys somewhat lower surface velocities over most of the frequency range, even though the input vibration at the pan rail is the same for the two engines.

As Fig. 7 shows, however, the aluminum pan's modest advantage in surface velocity does not translate into a noise advantage. In fact, the aluminum pan is about 10 dB louder at many frequencies. This difference is due entirely to higher radiation efficiency of the stiffer aluminum oil pan. The stamped steel pan enjoys a 7-dB lower overall A-weighted sound power than the much stiffer cast-aluminum pan.

In general, large covers with large, flat areas can benefit most from low stiffness. This is especially apparent with the heavy-duty diesel oil pan example. In this case, every factor works in favor of a less stiff design: first, there is a lot of high-frequency vibration at the pan rail, making it impossible to stiffen the pan so that natural frequencies are above the input frequency. Second, A-weighting favors low-frequency noise. Third, it is easy to achieve low natural frequencies of the pan and thus low radiation efficiencies, given the large, flat surfaces of a heavy-duty diesel oil pan. Smaller covers, on the other hand, may not achieve a noise advantage through low stiffness. Smaller, more complex shapes are inherently stiffer. It may not be possible to achieve the low stiffness required to get low radiation efficiency without sacrificing mechanical integrity of a small cover. However, small covers can often be stiffened

Figure 6 Comparison of mean square surface velocity for a stiff cast-aluminum oil pan and a relatively flexible stamped steel pan on the same heavy-duty diesel engine.

Figure 7 Comparison of radiated sound power level for a stiff cast-aluminum oil pan and a relatively flexible stamped steel pan on the same heavy-duty diesel engine.

to the point where the first resonance is beyond the frequency range of significant excitation. In many cases, it is not obvious whether increasing or reducing stiffness is a better noise reduction path. Design alternatives can be explored in hardware or by using noise radiation models, which will be described in Section 14.

Adding damping is another option for reducing noise of engine covers. Cast-aluminum and stamped steel covers tend to be highly resonant and lightly damped, so they may amplify the vibration fed into them from the engine structure. Constrained layer steel is widely used to add damping in oil pans, valve covers, and other engine components of both gasoline and diesel engines. Damping treatments are available for cast-aluminum components as well.

Covers can also be isolated from the engine structure to reduce noise. Isolation normally takes

the form of a soft gasket and grommets to avoid any metal-to-metal contact with the structure. The isolation system can be designed with a relatively low natural frequency, limited by the need to control the position of the component and to avoid leaks. Vibration reduction is greatest if there is a large impedance mismatch, so isolation systems work best between a stiff structure and a stiff cover. Isolated covers are common on both SI and CI engines.

13 NOISE SHIELDS AND ENCLOSURES

Shields and enclosures can be viewed as engineering Band-Aids. If the effort to reduce forcing functions, improve the structure, and improve covers does not achieve the required noise reduction, an engineer can always cover the problem up with a shield or enclosure. These components are normally isolated from the engine structure to prevent vibration transmission to

their surfaces. High damping and low stiffness are usually chosen to minimize noise radiation. Enclosures are typically mounted directly on the engine, while shields may be mounted on other nearby structures.

Shields and enclosures are not a noise reduction panacea. They tend to be expensive and heavy and can be very difficult to package in an engine installation. Even small gaps or holes will allow a significant amount of noise to escape, but enclosures must allow for plumbing, wiring, tool clearance, cooling airflow, and other openings. Once all the required openings are put into a shield, the noise reduction performance may be quite modest.

14 MODELING ENGINE NOISE GENERATION

Many noise sources have been successfully modeled, but engines have proven to be a very difficult source to model with a reasonable degree of accuracy. There are a number of reasons for this:

- The forcing functions can be difficult or impossible to simulate or measure experimentally.
- Both forcing functions and engine dynamics are often nonlinear and thus difficult to model.
- Many forces are transmitted through nonlinear oil films.
- It is not always clear where forces are applied to the structure, or which forces are important enough that they must be considered.
- The structure and covers are complex, offering multiple transmission paths.
- The many bolted joints of an engine create damping that is difficult to model accurately.

These difficulties apply just to calculating vibration velocities on the external surfaces of the engine. The task of calculating radiated noise remains.

A great deal of academic and industrial research has focused on modeling the noise generation of engines. As a result, a number of commercial software packages are available to deal with various aspects of the problem. First come models to predict the airflow and combustion behavior of the engine. This information is required in order to predict cylinder pressure, which is the driving force behind many engine noise forcing functions. Once cylinder pressure is known or predicted, other forcing functions must be modeled. Some models deal only with predicting the behavior of the crank train, and the resulting forces transmitted through the main bearings and oil films to the engine block. Other programs model the dynamics of valve trains or pistons, predicting the resulting force inputs. Elastohydrodynamic models of oil film behavior are an important element of these modeling programs, both to get the dynamics of the components right and to predict the forces put into the engine structure.

Once the forces being applied to the engine structure are understood, the next task is to model the structural response. This is normally done using widely

available finite element models. The models created for stress analysis are usually not appropriate for noise modeling because the large size of stress models leads to unacceptable run times for a dynamic analysis. A relatively coarse model of the engine structure is required. The known or predicted forcing functions are applied, and the dynamic response of the engine structure is calculated. The result is a velocity spectrum for each node in the model.

The final step is to predict the radiated noise, based on the velocities of the external surfaces. In doing this, radiation efficiency is directly or indirectly calculated. The most common approach is to create a boundary element model of the external surface. The velocities are entered as inputs, and overall sound power or sound pressure at specific locations can be calculated.

Boundary element models require considerable computational resources. There is a strong trade-off between model resolution (and thus the maximum frequency that can be accurately predicted) and run time. Other approaches may be considered. First, Rayleigh integral programs can predict overall radiated sound power with far less computational resources, but they cannot deal with calculating pressure at a point in space, or with noise in an enclosed space.¹⁸ Second, statistical energy analysis (SEA) can be used in situations where the modal density is high enough to allow individual modes and resonances to be ignored. This suggests that SEA is only valid at relatively high frequencies, but the lower frequency limit is a matter of debate.^{19,20} Alternative methods are also under development.²¹

A successful engine noise modeling effort is far from a plug-and-chug operation. It is easy to get a model to give the right answer for the wrong reasons. As a result, many experimental and analytical validation steps are required to show that each step of the modeling process is giving an accurate result, and that the assumptions made in the model are valid. Close cooperation between engineers doing the experimental and modeling work is essential. Only when models have been fully validated can they be used with any confidence to explore design alternatives.

1 INTRODUCTION

A muffler or silencer is a device used in a flow duct to prevent sound from reaching the openings of the duct and radiating as far-field noise. Reactive silencers reflect sound back toward the source, while absorptive silencers attenuate sound using absorbing material. Mufflers and silencers are necessary components used in the design of any exhaust or intake system for internal combustion engines. No car or truck can pass the standard noise tests required by legislation or compete on the market without their use. There are three basic requirements for a modern exhaust system: compact outer geometry, sufficient attenuation, and low pressure drop.

Different acoustical design and analysis techniques to predict the acoustical performance of internal combustion engine exhaust and intake systems have been in use for many years. These theories and techniques can be used also for other applications, such as compressors and pumps and to some extent also for air-conditioning and ventilation systems. Techniques are not yet available for the prediction of the acoustical performance of modern intake systems made from plastic material with nonrigid walls.

2 TYPES OF MUFFLERS

Two different physical principles are used for sound reduction in mufflers. Sound can be attenuated by the use of sound-absorbing materials in which sound energy is converted into heat mainly by viscous processes. Typical sound-absorbing materials used are rock wool, glass wool, and plastic foams. To force the exhaust flow through the absorbing material would create a large pressure drop so the material is usually placed concentrically around the main exhaust pipe; see Fig. 1. To protect the absorbing material and prevent it from being swept away by the flow, a perforated pipe is usually inserted between the main pipe and the absorbing material. Sometimes a thin layer of steel wool is included for additional protection. In some cases the outer chamber containing the absorbing material is flattened because of space limitations in fitting the muffler under a car; see Fig. 2.

The other physical principle used is reflection of sound, which is caused by area changes or use of

Figure 1 Typical exhaust system absorption muffler.¹

Figure 2 Absorption muffler of flat oval type.¹

Figure 3 Different types of resonators in a typical reactive automobile silencer: (a) $\lambda/4$ resonator and (b) Helmholtz resonator.¹

different kinds of acoustical resonators; see Fig. 3. These types of mufflers are called reactive. If the acoustic energy is reflected back toward the source, then the question is what happens with it once it

Figure 4 Different types of perforated muffler elements having both reactive and resistive character: (a) through flow, (b) cross flow, and (c) reverse flow.¹

reaches the source. It could of course be that the source is more or less reflection free, but this is not usually the case. If multiple reflections in between the source and the reactive muffler occur, the sound pressure level should build up in this region and cause an increase further downstream too. The answer to this apparent paradox is that a reactive muffler when properly used causes a mismatch in the acoustic properties of the exhaust system and the source to actually reduce the acoustic energy generated by the source.

There are also cases where resistive and reactive properties are combined in the same muffler element. All reactive muffler elements do, in fact, cause some loss of acoustic energy in addition to reflecting a significant part of the acoustic energy back toward the source. The losses can be increased, for instance, by reducing the hole size of perforates, especially if the flow is forced through the perforates. Figure 4 shows some typical perforate muffler elements, where especially the cross-flow and reverse-flow type have a significant resistive as well as reactive character.

3 DEFINITIONS OF MUFFLER PERFORMANCE

To assess the success of a new muffler design, there is a need for measures to quantify the sound reduction obtained. There are at least three such measures in

common use: transmission loss, insertion loss, and noise reduction.

The transmission loss (TL) is defined as the ratio between the sound power incident to the muffler (W_i) and the transmitted sound power (W_t) for the case that there is a reflection-free termination on the downstream side

$$TL = 10 \log(W_i / W_t) \quad (1)$$

This makes it difficult to measure transmission loss since an ideal reflection-free termination is difficult to build, especially if measurements are to be made with flow. There are measurement techniques^{2,3} that can be used to determine transmission loss by using multiple pressure transducers upstream and downstream of the test object. It is also necessary to make two sets of measurements either by using two acoustic sources, one downstream and one upstream of the test object, or by using two different downstream acoustic loads. The advantage of using transmission loss is, on the other hand, that it only depends on the properties of the muffler itself. It does not depend on the acoustic properties of the upstream source or the downstream load. Transmission loss can, therefore, also be calculated if the acoustic properties of the muffler is known without having to consider the source or load characteristics. Since the transmitted sound power can never be larger than the incident, the transmission loss must always be positive. A high transmission loss value tells us that the muffler has the capacity to give a large sound reduction at this frequency. It will not tell us how big the reduction will be since this depends on the source and load properties.

Insertion loss (IL) is defined as the difference in sound pressure level at some measurement point in the pipe or outside the opening when comparing the muffler element under test to a reference system:

$$IL = 20 \log(\tilde{p}_m / \tilde{p}_r) \quad (2)$$

where \tilde{p}_m is the root-mean-square (rms) value of the sound pressure for the muffler under test, and \tilde{p}_r is the rms value of the sound pressure for the reference system. It is common that the reference system is a straight pipe with the same length as the muffler element under test, but it could also be a baseline muffler design against which new designs are tested. Insertion loss is obviously easy to measure, as it only requires a sound pressure level measurement at the chosen position for the two muffler systems. It does, however, depend on both upstream acoustic source characteristics and downstream acoustic load characteristics. Insertion loss is, therefore, difficult to calculate since especially the source characteristics are difficult to obtain. Methods for determining source data will be further discussed in Section 6. Insertion loss has the advantage that it is easy to interpret. A positive value means that the muffler element under test is better than the reference system while a negative value means that it is worse.

Sound reduction (SR) is defined as the difference in sound pressure level between one point upstream of the muffler and one point downstream:

$$SR = 20 \log(\tilde{p}_u / \tilde{p}_d) \quad (3)$$

where \tilde{p}_u is the rms value sound pressure upstream of the muffler, and \tilde{p}_d is the rms value of the sound pressure downstream of the muffler. Just as insertion loss, sound reduction is easy to measure but difficult to calculate since it depends on source and load properties. The interpretation is less clear compared to transmission loss and insertion loss. It does tell us the difference in sound pressure level over the muffler for the test case, but the result may depend heavily on where the measurement positions are placed.

4 THEORETICAL DESIGN APPROACHES

Development of computer programs for acoustical design and analysis of flow ducts can be said to have started in the 1970s, although some codes were certainly in existence earlier. The low-frequency region is usually most important for Internal Combustion (IC) engine applications. This means that a one-dimensional or plane-wave approach is sufficient for the main exhaust and intake pipes. Most of the codes developed have used the so-called transfer matrix method,⁴⁻⁸ which is described in Section 4.1. This is a linear frequency-domain method that means that any nonlinearity in the sound propagation caused by high sound pressure levels is neglected. Local nonlinearity at, for instance, perforates can, however, be handled at least approximately. The assumption of linear sound propagation has experimentally been shown to be reasonably good.^{9,10} There are other analytical linear frequency-domain methods like the mobility matrix formulation¹¹ and the scattering matrix formulation,^{7,12} which have advantages for arbitrarily branched systems. Numerical methods such as the finite elements method (FEM)⁶ can also be used to solve the linear equations. They are especially useful for mufflers with complicated geometry and large cross-sectional area where the plane-wave propagation is no longer sufficient to describe the sound propagation in the frequency range of interest, but do increase the complexity of the calculations significantly. FEM should, therefore, only be considered as complement to the analytical methods for cases where they fail. Nonlinear time-domain techniques such as the method of characteristics or computational fluid dynamics (CFD) techniques^{6,13} have also been suggested. They are usually linked to a nonlinear model of the gas exchange process of the engine and are not really adapted for modeling muffler components even though some interesting attempts have been made. There are commercial codes available for simulating the engine gas exchange process that are in use by the automotive industry. They are an interesting alternative for obtaining information about the engine as an acoustic source, which will be further discussed in Section 6.

Figure 5 IC engine equipped with muffler and its acoustical representation.

4.1 Transfer Matrix Method

The transfer matrix method is an effective way for the analysis of sound propagation inside a duct network, especially if most of the acoustical elements are connected in cascade. The exhaust system of an internal combustion engine does in many cases have this kind of transmission line character. The method, which is often referred to as the four-pole method, was originally developed for the theory of electric circuits. To get a complete model accurate for analysis and design of exhaust systems, we must also take the influence of the sound source and the termination of the system into account. That is the sound generation and acoustic reflection characteristics of the engine as an acoustic source and the sound reflection and radiation characteristics of the termination. Using the assumptions of linearity and plane waves, the actual physical system with engine, exhaust system, and outlet can be described by a sound source, transmission line, and acoustic load; see Fig. 5.

The source is fully determined by the source strength P_s and the source impedance Z_s , which reveals how the source reacts to an arbitrary outer load such as an exhaust system. The load is described by a termination impedance. The source data and load data will be discussed further in Sections 6 and 7.

Three basic assumptions concerning the sound field inside the transmission line are made in the transfer matrix method. First, the field is assumed to be linear, that is, the sound pressure is typically less than one percent of the static pressure. This allows the analysis to be carried out in the frequency domain, and transfer function formulations can be used to describe the physical relationships. The assumption of linearity does not, however, mean that no nonlinear acoustic phenomena inside the system can be modeled. Some local nonlinear problems can, for example, be solved in the frequency domain by iteration techniques. The second assumption requires that the system within the black box is passive, that is, no

Figure 6 Exhaust system modeled with the transfer matrix method.¹

internal sources of sound are allowed. Finally, only the fundamental acoustic mode, the plane wave, is allowed to propagate at the inlet and outlet sections of the system. Provided the above-mentioned assumptions are valid, there exists a complex 2×2 matrix \mathbf{T} , one for each frequency, that completely describes the sound transmission within the system:

$$\begin{bmatrix} \hat{P}_1 \\ \hat{V}_1 \end{bmatrix} = \begin{bmatrix} t_{11} & t_{12} \\ t_{21} & t_{22} \end{bmatrix} \begin{bmatrix} \hat{P}_2 \\ \hat{V}_2 \end{bmatrix} \quad (4)$$

where \hat{P}_1 and \hat{P}_2 are the temporal Fourier transforms of the sound pressures, and \hat{V}_1 and \hat{V}_2 are the temporal Fourier transforms of the volume velocity at the inlet and the outlet, respectively. The major advantage with the transfer matrix method is the simplicity with which the transfer matrix for the total system is generated from a combination of subsystems, each described by its own transfer matrix; see Fig. 6.

The transfer matrix for a number of elements A_1, A_2, \dots, A_N connected in cascade is obtained from repeated matrix multiplication:

$$\mathbf{T} = \prod_{j=1}^N \mathbf{A}_j \quad (5)$$

This is a procedure that for long transmission lines is much more effective than solving a large system of equations, as will be the alternative if the mobility matrix formulation is used.

The division of the total system into more easily analyzed subsystems can be done in many different ways as long as the coupling sections between the elements fulfill two conditions. First, there must be continuity in sound pressure and volume velocity. This is achieved by choosing a suitable formulation of the transfer matrix, where the effects of discontinuities are included within the described element. Second, the coupling sections must not allow any higher order modes to propagate. This condition implies that the allowed frequency range for the classical transfer matrix method has an upper limit that coincides with the cut-on frequency for the first higher order mode in the coupling section. With modal decomposition the number of modes can easily be extended by increasing the dimension of the transfer matrix and accordingly the frequency range.¹⁴ Once the division of the system into acoustical elements has been done, the final task is to generate the total transfer matrix. This is done

in analogy with the theory of electric circuits, that is, by regarding the system as a network of cascade- or parallel-coupled elements. In exhaust systems, most of the elements are usually connected in cascade, and the transfer matrix formulation is, therefore, especially powerful for this application.

5 MODELING OF MUFFLER ELEMENTS

5.1 Straight Ducts

A typical automobile exhaust system consists of two or three silencers connected by ordinary sheet steel pipes. These are usually straight or slightly curved with circular constant cross section (diameter typically around 50 mm) and wall thickness of 1 to 1.5 mm. A truck system typically has pipes with 100-mm to 150-mm diameter. To be able to use the transfer matrix or scattering matrix method, only plane waves should propagate in the pipes. The expression for the cutoff frequency of the first higher order mode in a circular cross section pipe is given by

$$f^c = \frac{1.841c}{\pi d} \quad (6)$$

where c is the speed of sound and d is the duct diameter. The cutoff frequency for a typical automotive system would, therefore, be above 4 kHz and for a truck system it would be above 1.3 kHz at room temperature. In the exhaust systems the temperatures will be higher, which means that the speed of sound and the cutoff frequency will increase. For the typical curvatures and diameters, the influence of the bends may be neglected in the frequency range of interest: 30 to 2000 Hz.¹⁵

The solution for the sound pressure and volume velocity can in the frequency domain be written as

$$\hat{p} = \hat{p}_+ \exp(-ik_+z) + \hat{p}_- \exp(ik_-z) \quad (7)$$

$$\hat{V} = \frac{S}{\rho_0 c'} \{ \hat{p}_+ \exp(-ik_+z) - \hat{p}_- \exp(ik_-z) \} \quad (8)$$

where \hat{p}_+ and \hat{p}_- are the wave amplitudes, z is the coordinate in the propagation direction, S is the cross-sectional area, k_+ and k_- are the complex wavenumbers representing downstream and upstream propagating waves,^{16,17} respectively,

$$k_+ = k \frac{K_0}{1 + MK_0} \quad (9)$$

$$k_- = k \frac{K_0}{1 - MK_0} \quad (10)$$

where K_0 is given by

$$K_0 = 1 + \frac{1+i}{s\sqrt{2}} \left(1 + \frac{\gamma-1}{\sigma} \right) \quad (11)$$

and γ is the specific heat coefficient ratio, $\sigma = \sqrt{\mu C_p / \kappa}$ is the Prandtl number, $s = (d/2)\sqrt{\rho_0 \omega / \mu}$ is the shear wavenumber, μ is the shear viscosity coefficient, κ is the thermal conductivity coefficient, C_p is the specific heat coefficient for constant pressure, ρ_0 is the density, and d is the duct diameter. These expressions include the effect of viscous and thermal boundary layer losses and losses due to turbulence. Equations (9) to (11) are valid for large s and small M , typically $M < 0.3$ and $s > 40$. Howe¹⁸ has presented a theory with wider application range but yielding more complicated expressions.

Following the notation of Section 4.1 denoting the inlet or source side 1 and the outlet side 2, the transfer matrix is given by

$$\begin{aligned} t_{11} &= \frac{1}{2} \{ \exp(ik_+ \ell) + \exp(-ik_- \ell) \} \\ t_{12} &= \frac{\rho_0 c}{2S} \{ \exp(ik_+ \ell) - \exp(-ik_- \ell) \} \\ t_{21} &= \frac{S}{2\rho_0 c} \{ \exp(ik_+ \ell) - \exp(-ik_- \ell) \} \\ t_{22} &= \frac{1}{2} \{ \exp(ik_+ \ell) + \exp(-ik_- \ell) \} \end{aligned} \quad (12)$$

In the long pipes between the different silencers there may be temperature gradients. This problem can be solved by dividing the pipe into a number of elements, each with a constant but different temperature, and thus obtain the desired temperature gradient.¹⁹

5.2 Dissipative Muffler Elements

A typical dissipative exhaust system muffler is shown in Fig. 1. The most simple approach that can be used for this kind of muffler is that the walls are locally reacting, that is, each point in the wall acts as if it were completely isolated from the rest of the wall.²⁰ This is often a good assumption in the case of walls covered with porous material, but it is an approximation. The alternative is to use an extended reaction model where sound propagation in the liner is considered. The locally reacting wall is characterized by a locally reacting impedance, Z_w . The linear, nonviscous, adiabatic sound field within a duct with locally reacting walls can be found from the wave equation by adding a source term.²⁰ This term is really originating from the equation of continuity, where it accounts for the volume velocity through the walls. It should be noted that this approach is really one-dimensional and the wave is thus still plane, as discussed above. The solution in the frequency domain may be expressed in a way similar to the solution in (7) and (8), but with different wavenumbers:

$$\begin{aligned} k_{\pm} &= \pm \frac{i}{1 - M^2} \left\{ ikM + \frac{\rho_0 c M}{2Z_w S} \right. \\ &\quad \left. \mp \sqrt{\left(\frac{\rho_0 c M}{2Z_w S} \right)^2 + \frac{ik\rho_0 c}{Z_w S} - k^2} \right\} \end{aligned} \quad (13)$$

The upper sign represents the downstream wave and the lower sign represents the upstream wave.

In a conventional dissipative automobile silencer (Fig. 1), the porous material is covered by perforated sheet steel. Thus Z_w really consists of two impedances, the porous material Z_a and the perforated shielding Z_p . The acoustic effect of the perforations can, however, be neglected if the porosity, that is, the percentage open area, is higher than around 20%. This is often true if the perforated pipe was included just to guide the flow and keep the absorbing material in place and not to have any acoustic effect. For the description of the porous material the model according to Zwikker and Kosten²¹ can be used. An extensive description of different models for the acoustical properties of porous materials is given in Ref. 22. In the Zwikker–Kosten model the effects of the porous material on acoustic motion are included in the equations of motion and conservation of mass through three parameters. The first is called porosity, Ω , and accounts for the obvious fact that a specific volume is no longer completely occupied by the fluid; there is also a solid structure. The fluid within the porous material can only propagate along certain paths, which means that the reaction of some fluid particle to a pressure gradient not necessarily needs to be in the direction of the gradient. Provided these paths are randomly oriented, that is, the absorber is isotropic, this effect is described by the structure factor, χ . Finally, the increased friction within the fluid due to the solid structure is considered by the flow resistivity ϕ . The following impedance as seen from the duct toward the lining can be deduced,

$$Z_a = -i\rho_e c_e (\omega h / c_e) \quad (14)$$

where h is the thickness of the lining, ρ_e is the effective density, and c_e is the effective speed of sound. These are given by

$$\rho_e = \rho_0 \left(\frac{\chi}{\Omega} - \frac{i\phi}{\omega\rho_0} \right) \quad (15)$$

$$c_e = \frac{1}{\sqrt{\rho_e \kappa_p \Omega}} \quad (16)$$

In this expression κ_p is the compressibility for the porous material, which for low frequencies behaves more or less isothermally due to the heat conduction between solid and fluid. At higher frequencies the acoustic motion is very fast, no heat conduction can appear, and the motion is adiabatic. These assumptions are verified experimentally,²³ and usually the true compressibility lies somewhere between κ_T and κ_s .

5.3 Perforated Muffler Elements

Perforated tubes are commonly found in automotive mufflers. Two basic configuration examples are shown in Fig. 7. In a commercial muffler the configuration

Figure 7 Basic muffler configurations.

Figure 8 Examples of commercial perforated mufflers.

is usually much more complicated, as illustrated in Figs. 8 and 9.

Perforates can be used to confine the mean flow in order to reduce the back-pressure to the engine and the flow generated noise inside the muffler, such as in the through-flow configuration. Ideally, perforates are then acoustically transparent and permit acoustic coupling to an outer cavity acting as a muffler. Perforates can also be used to create losses when the flow is forced through the perforates, such as for the plug flow configuration. Being able to theoretically model these mufflers enables car manufacturers to optimize their performance and increase their efficiency in attenuating engine noise. Therefore, there has been

Figure 9 Effect of coupling condition and Mach number on the transmission loss of the through-flow muffler.³⁵

a lot of interest to model the acoustics of two ducts coupled through a perforated plate or tube. Generally, the modeling techniques can be divided into two main groups, the distributed parameter approach and the discrete or segmentation approach.

In the distributed approach, the perforated tube is seen as a continuous object, and the local pressure difference over the tube is related to the normal particle velocity via surface-averaged wall impedance. The main challenge facing this approach is the decoupling of the equations on each side of the perforate. Using this approach results in closed-form expressions for the acoustic transmission, and therefore the calculations are very fast. Sullivan and Crocker²⁴ presented the first analysis of this approach. They only considered through-flow concentric resonators with the flow confined in the main duct. They did not have the decoupling problem because the flow inside the cavity was assumed to be zero. Therefore, their model cannot be applied to situations with cross flow. Moreover, it does not work for nonrigid boundary conditions at the side plates of the muffler, for example, extended inlet and outlet configurations.

Later, Jayaraman and Yam²⁵ introduced a decoupling approach based on a mathematical assumption that requires the mean flow Mach number to be equal on both sides of the perforate. This is considered a major disadvantage because this case is hardly found in practice. The two Mach numbers are in inverse proportion to the cross-sectional area of the two ducts, which are usually different. Rao and Munjal²⁶ presented a method to overcome this problem with a generalized decoupling analysis that allows for different flow Mach numbers in the two pipes. They used the same equations as Sullivan and Crocker.²⁴ They also extended the method to be able to handle any boundary conditions at the muffler end plates. Peat²⁷ pointed out that their decoupling conditions are only satisfied for the two simple cases of $M_1 = M_2 = 0$ or $M_1 = M_2$. He was unable to find analytical expressions that fully satisfy the generalized approach and hence resorted to

a numerical decoupling solution. Munjal et al.²⁸ presented a first attempt to use the numerical decoupling technique, but they reported problems of numerical instabilities close to the peaks of the transmission loss. Peat²⁷ derived more general equations than all previous models by allowing the Mach number and impedance to vary along the length of the perforate. This generalization contains some of the properties and advantages of the segmentation approach. He only made calculations using constant parameters. Numerical decoupling overcomes the modeling deficiencies of the analytical techniques, introducing an additional cost in terms of computing time as it requires solving an eigenvalue problem. Dokumaci²⁹ developed a new approach for numerical implementation of the distributed parameter method based on the so-called Matrizant theory. This approach is comparable to Peat's numerical decoupling method in that an eigenvalue problem has to be solved; however, it is able to correctly handle a mean flow velocity gradient that was earlier a shortcoming of the distributed parameter methods. Dokumaci criticized Peat's method pointing out that a gradient term appears to be missing in the governing equations, and that he neglected the mean flow variation in some terms that might be of the same order as the retained terms. There was a published correspondence on this issue.³⁰

Finally, Dokumaci²⁹ concludes that "the distributed parameter theory of plane wave propagation in a perforated pipe provides a more satisfactory setting than the segmentation method for the analysis of the effects of axially varying quantities such as the mean flow velocity." But later, Dokumaci³¹ himself stated that "the discrete approach is computationally simpler and more versatile than the more commonly known distributed parameter method."

The discrete or segmentation approach was first developed by Sullivan.^{32,33} In this approach, the coupling of the perforate is divided into several discrete coupling points with straight hard pipes in between. Each segment consists of two straight hard pipes and a coupling branch. The total 4×4 transmission matrix of the perforated element is found from successive multiplication of the transmission matrices of each segment. Kergomard et al.³⁴ used this concept and presented, for the case of two waveguides communicating via single holes, a model for wave transmission in a periodic system. Dokumaci³¹ presented another discrete approach based on the scattering matrix formulation. He discussed several possibilities for modeling the connecting branch. He proposed a continuous viscothermal pipe model, a continuous isentropic pipe model with end corrections, and a lumped impedance model (as in Sullivan). The conclusion was that the lumped-element model is the most appropriate for this problem. He sometimes added a correction to the segment length so that his results match Sullivan experiments. It was unclear how he determined this end correction and on what basis he includes it or not.

The distributed approach is mainly convenient for relatively simple perforated mufflers. There are, however, many complicated muffler configurations in

which perforations are used in nonstandard ways. The discrete approach is more convenient to analyze advanced muffler systems because of numerical simplicity and flexibility. It is also straightforward to model gradients in mean flow and temperature using this approach, and as demonstrated in³³ arbitrary complex perforated systems can be also handled. One main difference between the distributed and discrete approaches is the definition of the coupling conditions over the perforate. In the distributed approach, continuity of acoustic momentum is usually imposed, whereas in the discrete approach, continuity of acoustic energy is usually assumed. Recently, Aurégan and Leroux³⁵ presented an experimental investigation of the accuracy of these coupling conditions with flow. They demonstrated that neither continuity of momentum nor energy seems to be strictly valid. Aurégan and Leroux suggested that the coupling condition should be something in between conservation of energy and conservation of momentum. The sensitivity of the results to the assumption of the coupling condition was investigated by Elnady³⁶ using a generalized segmentation model based on Sullivan's approach. This general model is able to use any specified coupling condition based on a single parameter, α , which has the value of 1 for continuity of energy, 2 for continuity of momentum, or can be assigned any value in between. The sensitivity of the transmission loss results were compared for the simple muffler configurations shown in Figs. 7 and the results are shown in Figs. 9 and 10.

The effect of flow on the transmission loss caused by the increased resistance when the flow is forced through the perforates can be clearly seen in Fig. 10. It can also be seen that the choice of coupling condition is of importance for these simple mufflers. A complicated multichamber muffler was also analyzed in Ref. 36. See Fig. 11.

A comparison between measured and predicted transmission loss at 0.15 Mach is shown in Fig. 12. A reasonable agreement between measured and predicted results is obtained. It can also be seen that the

Figure 10 Effect of coupling condition and Mach number on the transmission loss of the plug flow muffler.³⁵

Figure 11 Sketch of complex perforated muffler analyzed.³⁵

Figure 12 Comparison between measured and calculated transmission loss at $M = 0.15$ for complex perforated muffler analyzed.³⁵

choice of coupling condition is much less important in this case. The reason is probably that a number of other parameters besides the losses caused by flow through the perforates are important for the complex muffler. These losses are, however, very important for obtaining the high transmission loss over the wide frequency band seen in Fig. 12.

5.4 Expansion Chambers

The dimensions of a typical exhaust expansion chamber usually makes it necessary to consider the effects of propagating higher modes for an analysis in the usual frequency range of interest, 30 to 2000 Hz. Since typical expansion chambers are quite short, the losses due to viscosity and heat conduction can be neglected along with the flow-acoustic interaction, which may occur especially at the inlet and outlet regions. The convection can also be neglected for typical Mach numbers even if it is accounted for in one of the models discussed below. A simple analytical approach, such as mode matching,³⁷ can often be used for ducts of cross-sectional shape and boundary conditions for

which the solutions to the wave equation form a complete set of eigenfunctions. These functions are usually very complicated, and accordingly the method is most suited for cases where the eigenfunctions are orthogonal. This analysis is carried out for ducts of circular cross section, and cylindrical coordinates (r, ϕ, z) are chosen in which the boundary condition of nonflexible walls are easily formulated. As an extension to Eq. (7) the three-dimensional solution to the wave equation can be written as a mode sum:

$$\hat{p} = \sum_n \{ \hat{p}_n^+(r, \phi) \exp(-ik_n^+ z) + \hat{p}_n^-(r, \phi) \exp(ik_n^- z) \} \quad (17)$$

where \hat{p}_n^+ and \hat{p}_n^- are the eigenfunctions for the duct cross section, and k_n^+ along with k_n^- are the longitudinal wavenumbers for each mode as determined by the boundary conditions, where $n = 0$ generates the usual plane wave. Two different types of chambers, flush-mounted inlet and outlet and concentric inlet and outlet will be discussed below.

5.4.1 Eccentric Inlet and Outlet This configuration of a circular expansion chamber (Fig. 13) with the inlet and outlet mounted in plane with the end walls but otherwise arbitrarily has been treated by Ih and Lee³⁸ using the assumptions above, although including the convective effect of mean flow. The influence of higher order modes in the inlet and outlet ducts is completely neglected in their analysis, that is, only the end corrections toward the chamber are included. The approach is similar to that of a duct with one closed nonflexible end and the other driven by a plane piston. To match the field inside the chamber with the incident, reflected and transmitted plane waves, it is averaged over the inlet and outlet cross-section areas.

5.4.2 Extended Inlet and Outlet Another common type of expansion chamber (Fig. 14) is with extended inlet and/or outlet, forming a annular $\lambda/4$ resonator with the end plates.

Figure 13 Expansion chamber with flush-mounted eccentric inlet and outlet.

Figure 14 Expansion chamber with concentric extended inlet and outlet.

To simplify the analysis the inlet and outlet are assumed to be mounted concentrically, and further all effects of mean flow are neglected. This analysis using the mode-matching technique is explained in detail by Åbom.³⁹ It should be noted that higher modes are included not only in the main chamber but also in the $\lambda/4$ resonator region and in the inlet and outlet ducts, although only plane waves are assumed to be incident on the chamber in these ducts. The number of analyzed modes is prescribed for the main chamber and the number of modes in the other regions, required for accurate analysis, is then given by the so-called edge condition.³⁸

5.5 Area Discontinuity Muffler Elements

The analysis of sound propagation through sudden changes in the cross-section area of a flow duct is complicated in the case of superimposed mean flow. This is due to the interaction between the mean flow field and the acoustic field in these regions. From the theoretical point of view, the problem is that the actual mean flow velocity profile near the expansion or the contraction is too complicated to allow any exact analytical approach, at least so far.

However, by assuming a simpler velocity profile, the problem has still been treated in a number of references.^{14,40,41} The original assumption, made by Ronneberger,⁴⁰ is that the distance over which the mean flow is expanded or contracted is negligible compared to the acoustic wave length. This assumption is also adopted by Alfredson and Davies⁴² and will be used here, as it enables the transmission properties of the area discontinuity to be formulated (Fig. 15). Another assumption, introduced by Cummings⁴¹ is that the velocity profile reacts more slowly to the change in area. For a typical expansion chamber this means that the mean flow “jet” entering the chamber is not assumed to expand in the short distance between inlet and outlet of the chamber. The analysis using both these assumptions is one-dimensional and valid for quasi-steady conditions, including the irreversible losses due to turbulence in the conservation of energy. A three-dimensional more rigorous and extensive analysis has been presented by Nilsson and Brander¹⁴ imposing a strict Kutta condition at the area discontinuity. In this theory the hydrodynamic modes, which are excited at the sudden expansion but further downstream turned into turbulence, are included. For exhaust systems, where

Figure 15 Mean flow velocity profile of an area expansion and control volume for quasi-stationary analysis according to (a) Ronneberger⁴⁰ and (b) Cummings.⁴¹

the Mach numbers typically are less than 0.1 and the analysis is restricted to rather low frequencies, it has been found that the differences between the different formulations are small. The simple analysis of Alfredson and Davies is quite accurate for this application, although the acoustic near-field effects have to be included. In the following analysis these effects are added as indicated by Davies⁴³ and Lambert and Steinbrueck⁴⁴ using Karal's end correction.⁴⁵ The usual silencer element where the inlet or outlet are extended into the larger duct is also modeled. The analysis includes both positive and negative mean flow, and application to an intake system is therefore also possible.

5.5.1 Area Contraction The transfer matrix expression given below was derived following the assumptions indicated above and regarding the acoustic wave as a one-dimensional quasi-stationary perturbation of the mean flow and further assuming adiabatic contraction and positive isentropic flow. This means that losses caused by flow separation at the flow contraction has been neglected. This is an approximation but is usually justified. The following transfer matrix C is obtained over the control volume given in Fig. 15:

$$\begin{aligned} t_{11} &= 1 - \frac{M_1 \rho_0 c}{z S_1 (1 - M_1^2)} \\ t_{12} &= \rho_0 c \frac{(S_1/S_2 - S_2/S_1) M_1 - \rho_0 c M_1^2 / z S_2}{S_2 (1 - M_1^2)} \\ &\quad + m_{12} \frac{1 - \rho_0 M_1}{z S_1 (1 - M_1^2)} \\ t_{21} &= \frac{1}{z (1 - M_1^2)} \\ t_{22} &= \frac{1 - (M_1^2 + \rho_0 c M_1 / z S_1) (S_1/S_2)^2}{1 - M_1^2} \\ &\quad + \frac{m_{12}}{z (1 - M_1^2)} \end{aligned} \quad (18)$$

where $m_{12} = i \omega \rho_0 \Delta_e / \pi a^2$ and index 1 is for the inlet side and index 2 for the outlet side. The boundary condition of a nonflexible end wall is in the case of extended outlet replaced by an impedance condition given by $\lambda/4$ resonator of length equal to the distance between the outlet opening and the end wall ℓ :

$$Z = -i \rho_0 c \cot\{k(\ell + \Delta_e)\} \quad (19)$$

To estimate the effects of the acoustic near field at the area discontinuity, we use the end correction according to Karal, which is deduced in the case of no mean flow for a contraction, or expansion, in a circular duct. For the extended outlet/inlet case, this correction will be slightly too large, although sufficiently accurate for this application according to

Davies.⁷ The correction acts as an extra length added to the smaller duct. The end correction Δ_e is given as

$$\Delta_e = 8H(\alpha)a/3\pi \quad (20)$$

with

$$H(\alpha) \approx 0.875(1 - \alpha)(1.371 - \alpha) \quad 0.5 \leq \alpha \leq 1.0$$

$$H(\alpha) \approx 1 - 1.238\alpha \quad 0 \leq \alpha \leq 0.5$$

and α as the ratio of the duct diameters (smaller/larger).

As there are only plane waves propagating, we have in Eq. (18) made the following definition:

$$z = Z/|S_1 - S_2| \quad (21)$$

For intake systems where the mean flow is in the opposite direction to the sound propagation, there will be turbulent losses at an acoustic contraction, and the problem is similar to that of an exhaust system area expansion, which is treated in the next section. To obtain the desired four-pole, we only have to change the sign of the volume velocity and invert the transfer matrix for an expansion with positive mean flow.

5.5.2 Area Expansion In the case of an area expansion, we have to consider the irreversible turbulent losses that occur at the discontinuity due to the expanding mean flow. Including a corresponding change in entropy, the following transfer matrix is obtained:

$$\begin{aligned} t_{11} &= \frac{1 + \{\gamma(1 - S_1/S_2)^2 - 1\}M_1^2}{\det} \\ &\quad + m_{12} \frac{1 + \gamma(M_1 S_1/S_2)^2}{z \det} \\ t_{12} &= \frac{2\rho_0 c M_1 (S_1/S_2 - 1)}{S_2 \det} \\ &\quad + m_{12} \{1 + (M_1^2 S_1/S_2)(1 - 2S_1/S_2) \\ &\quad + 2\rho_0 c M_1 S_1/S_2^2 z\}/\det \\ t_{21} &= \frac{1 + \gamma(M_1 S_1/S_2)^2}{z \det} \\ t_{22} &= \{1 + M_1^2 S_1(1 - 2S_1/S_2)/S_2 \\ &\quad + 2\rho_0 c M_1 S_1/z S_2^2\}/\det \end{aligned} \quad (22)$$

where

$$\begin{aligned} \det &= 1 + M_1^2 \{\gamma - 1 + (\gamma - 1)(S_1/S_2)^2 \\ &\quad + (1 - 2\gamma)S_1/S_2\} + 2\rho_0 c M_1/S_2 z \end{aligned}$$

As above, for the intake system application with negative mean flow, the transfer matrix can be obtained from the transfer matrix for a contraction with positive

mean flow. Due to reciprocity, which is known to be valid in the case of no irreversible losses, no inversion is necessary, and the desired transfer matrix is obtained from Eq. (18) by simply shifting notations 1 and 2.

5.6 Horn Muffler Elements

A smooth expansion or contraction in a flow duct, that is, a horn is often used to decrease the pressure drop in an exhaust system. Neglecting losses, mean flow, and higher modes and further considering the walls of the horn to be nonflexible, the wave equation can be integrated to yield Webster's horn equation.⁴⁶ Simple analytical solutions to this equation only exist for a few types of horns, where the cross-section area (or radius) is some simple function of the length coordinate, $S = S(z)$. A typical example is the exponential horn where $S = S_0 \exp(mz)$, where m is called the flare constant. Another example, which we will refer to later, is the conical horn where the radius of the circular cross section is linearly dependent on the length coordinate, $r = a_0 + k_0 z$. To allow for an arbitrarily varying cross section, the approach used above for temperature gradients can be applied. The horn is divided into a number, N , of short "ordinary pipes" connected in cascade and continuity in pressure, and volume flow is assumed. Thus, this formulation extends the analysis to, in an approximate manner, include also mean flow and losses. Although this method has been successful in other applications as well, see, for instance Åbom,⁴⁷ no formal proof has been found for the convergence.

It should finally be mentioned that Doak and Davies⁴⁸ have presented an analysis of sound propagation in horns including the effects of mean flow. They also suggest that their solution replaces the straight pipe solution used above in order to reduce the number of segments, N .

5.7 Resonators

Traditionally, resonator silencers were mostly used for IC engines running at constant speed. The increasing demand for silencers with low pressure drop but still sufficient low-frequency attenuation has, however, made resonators more frequently used in automobile exhaust systems, especially in combination with dissipative silencers. The resonator silencer is very efficient regarding maximum attenuation versus pressure drop. The major disadvantages are the rather narrow frequency bands for which this attenuation occurs and the sensibility to variations in temperature. There may also be flow-acoustic interaction that causes the resonator to "sing." The acoustical concept of the resonator and, in fact, of all reactive silencers is to create a discontinuity in impedance along the flow duct, which causes a reflection of the propagating wave. For resonators this is achieved at the frequencies where the resonator mounted in the duct wall has zero impedance, neglecting losses, as seen from the flow duct, that is, at resonance. The following analysis is restricted to applications where the orifice of the resonator, which sometimes is called the mouth, and the diameter of the flow duct are small compared to the wavelength. The pressure is, therefore, uniform at the orifice and equal

to the upstream and downstream values, thus indicating a lumped description. The transfer matrix for this element of no extension along the transmission line is easily formulated:

$$\begin{aligned} t_{11} &= 1 \\ t_{12} &= 0 \\ t_{21} &= S_r/Z_r \\ t_{22} &= 1 \end{aligned} \quad (23)$$

where Z_r is the impedance of the resonator as seen from the flow duct and S is the area of the resonator mouth. Three different resonators are now described. Due to the restriction mentioned above and the fact that resonators mainly are silencers for tonal low-frequency noise, the models used in these sections are only valid in the low-frequency region, where the fundamental tone and the first harmonics are present.

5.7.1 Helmholtz Resonator The Helmholtz resonator is the most common type of resonator due to its geometrical compactness. This really means that it is possible to design a quite small Helmholtz resonator with a low-resonance frequency. It should be noted, however, that the efficiency of the resonator is related to the size, and rigorous design is necessary.

The Helmholtz resonator is the acoustical counterpart to the mechanical mass-spring system where the fluid in the neck is equivalent to the mass and the fluid in the cavity is equivalent to the spring. This lumped description is, of course, only valid as long as the wavelength is large compared to the dimensions of cavity and neck. Assuming the motion to be adiabatic, the impedance for the Helmholtz resonator can be written as

$$\begin{aligned} Z_{hr} &= R_{tu} + R_v + i\omega\rho_0(\ell_n + \Delta_i + \Delta_o) \\ &\quad - i\rho_0c^2 S_n/\omega V \end{aligned} \quad (24)$$

where ℓ_n and S_n are the length and cross-section area of the neck, respectively; see Fig. 16; Δ_i , and Δ_o are the end corrections due to the inner and outer near field as given by⁴⁶

$$\Delta_i + \Delta_o = 0.85a(1 + \varepsilon) \quad (25)$$

where ε is given by the following relations:

$$\begin{aligned} \varepsilon &= 1 - \frac{V_f}{fd_p} \leq \frac{0.24a}{d_p} \\ \varepsilon &= \left(1 + 0.3\frac{d_p}{a}\right) \\ &\quad \times \exp\left(\frac{0.24a/d_p - V_f/fd_p}{0.25 + d_p/2}\right) \\ &\quad - 0.3\frac{d_p}{a} \quad \frac{V_f}{fd_p} > \frac{0.24a}{d_p} \end{aligned}$$

Figure 16 Different types of resonators within a typical reactive automobile silencer: (a) $\lambda/4$ resonator and (b) Helmholtz resonator.

where V_f is the friction velocity and equals $V_0\sqrt{\psi/2}$ for a fully developed turbulent flow. V is the volume of the cavity and finally R_{tu} and R_v are the turbulent and viscous losses at the mouth assuming a circular cross section. Obviously, maximum attenuation is obtained for $\omega = c\sqrt{S_n/V(\ell_n + \Delta_i + \Delta_o)}$. The amount of attenuation is related to the losses, which determines how resonant the system is.

5.7.2 $\lambda/4$ Resonator The closed-pipe or $\lambda/4$ resonator is also a frequently used resonator silencer in exhaust systems, especially in combination with other elements such as expansions and contractions; see Fig. 16. The resonant behavior is generated by the incident wave reflected at the closed end of the resonator. The efficiency of all resonators is, besides the mouth geometry, also dependent on the stiffness of the walls. This is a difficult problem due to the wave motion of the walls. In this simple model only the end wall is allowed to be flexible, introducing a frequency-independent reflection coefficient, \Re . Restricting the analysis to the plane-wave region and further adopting the flexible end wall boundary condition $\Re = \hat{p}_-/\hat{p}_+$ gives

$$Z_{sr} = \rho_0c \frac{\exp(ik\ell) + \Re \exp(-ik\ell)}{\exp(ik\ell) - \Re \exp(-ik\ell)} \quad (26)$$

where ℓ is the sum of the geometrical length ℓ_g of the resonator, and the end correction, which for a resonator mounted flush in the wall of a duct is given by Δ_i in Eq. (25). As the end correction is related to the geometry of the orifice, which is small compared to the length for a typical $\lambda/4$ resonator, it can usually be neglected. k is the wavenumber. The viscothermal and turbulent losses at the mouth can be included as for the Helmholtz resonator. As seen from Eq. (26) the $\lambda/4$ resonator will decrease the amplitude of the fundamental tone, $f_0 = c/4\ell$ and every even harmonic, $(2n+1)f_0$ where $n = 1, 2, \dots$, as long as no higher modes are propagating in the resonator pipe.

5.7.3 Conical Resonator The conical resonator (Fig. 17) is similar to the $\lambda/4$ resonator but has the advantage that it also attenuates the odd harmonics. Even though a conical silencer was patented already in 1935,⁴⁹ it has not been used a lot probably due to its

Figure 17 Conical side branch resonator.

rather bulky geometry. The acoustical properties can be estimated from Webster's horn equation, which for a linear cone, see Section 5.6, has a simple analytical solution:

$$\hat{p} = [\hat{p}_+ \exp(-ikz) + \hat{p}_- \exp(ikz)] / \sqrt{S_r} \quad (27)$$

where S_r is the inlet area/mouth of the conical side branch. The impedance of the conical resonator is given by

$$Z_{cr} = \frac{i \rho_0 c}{\cot(k\ell) - 1/k\ell} \quad (28)$$

where ℓ as before is the acoustical length, that is, the sum of the geometrical length, see Fig. 12, and the end correction for the cone. For a long and narrow cone it is probably an accurate assumption to use the end correction obtained for the $\lambda/4$ resonator.

5.8 After-Treatment Devices

Modern diesel engine exhaust systems often have after-treatment devices including both catalytic converters and diesel particulate traps. See Fig. 18.

5.8.1 Catalytic Converters Automobile catalytic converters became standard on cars in both the United States and Europe during the 1990s. The key

element in a typical automobile catalytic converter is the honeycomb structure in which the oxidation or reduction of the exhaust gases takes place. It consists of a large amount of parallel capillary pipes coated with aluminum oxide and a catalyst (e.g., platinum). A number of models normally expressed in the form of a two-port have been presented for the acoustics of such devices. One of the first attempts to present an acoustical model was made by Glav et al.⁵⁰ The model is based on an ad hoc combination of a classical formula for damping in narrow pipes with no flow with a model for flow-induced damping. A number of improved models have been presented, and for practical applications the most useful are perhaps the works of Dokumaci.^{16,51} In Ref. 16 he showed that the equations for sound propagation in a thermoviscous fluid, simplified in the manner of the Zwikker and Kosten theory,²¹ could be solved exactly for a circular pipe with plug flow. This result was used to analyze the sound propagation in catalytic converters. However, the cross section of the narrow pipes in a catalytic converter is close to quadratic. Therefore, in a later paper⁵¹ Dokumaci extended the model to rectangular cross sections by expanding the solution in terms of a double Fourier sine series. The effect of strong axial temperature gradients at the inlet has been treated by Peat,^{52,53} and the results show a marked effect on the attenuation and noticeable effect on the phase speed. The effect of temperature gradients dominates over the effect of flow convection at low shear wavenumbers.

The transfer matrix of a catalytic converter (CC) can be split into three different parts, the inlet cross section (IN), the narrow pipes with hard impermeable walls, and the outlet cross section (OUT):

$$T_{CC} = T_{IN} T_P T_{OUT} \quad (29)$$

The IN and OUT sections represent coupling two-ports, which are needed since pressure and volume

Figure 18 Sketch of a modern diesel engine after-treatment device containing both catalytic converter and diesel particulate filter.

velocity are not continuous at a sudden area change with flow. The two-port for the narrow pipe section is obtained using the model proposed by Dukomaci.¹⁶ The IN and OUT two-ports are obtained by applying the principle of conservation of energy and momentum, respectively. Since the Mach number in the CC section is very small, in practice (<0.05), these relations can be derived assuming an incompressible mean flow. The resulting two-ports are given in Ref. 54.

A point that can be made concerning the previous publications on CCs is that a large focus is put on the effect of mean flow on the damping. However, in typical exhaust systems the Mach number in the main pipe is normally less than 0.3. Then since the area expansion ratio into the CC section is typically of the order of 10, the Mach number into a CC is normally less than 0.03. This implies that the mean flow effects in practice are quite small and can be neglected. In addition since the cross-sectional shape of the CCs channels is quadratic the wave damping of a circular section with the same hydraulic diameter should be a good approximation. Therefore, as an alternative to the Dukomaci model, the two-port for the narrow pipe section can be calculated using the classical Kirchhoff solution for narrow pipes.⁵⁵ This implies

$$T_P = \begin{bmatrix} \cos(k_p L_p) & (i Z_p / N) \sin(k_p L_p) / Z_p \\ i N \sin(k_p L_p) / Z_p & \cos(k_p L_p) \end{bmatrix} \quad (30)$$

where $k_p = \omega / c_p$ is the wavenumber, L_p is the length of the CC section, $Z_p = \rho_p c_p / S$, and N is the number of channels; the density and speed of sound are calculated based on the Kirchhoff solution for each narrow pipe:

$$\rho_p = \frac{\rho_0}{1 - F(s)} \quad (31)$$

$$c_p = c_0 \frac{\sqrt{1 - F(s)}}{\sqrt{1 - (\gamma - 1)F(s)}} \quad (32)$$

where c_0 is the adiabatic speed of sound, $\sigma = \sqrt{\mu C_p / \kappa}$ is the Prandtl number, κ is the thermal conductivity coefficient, C_p is the specific heat coefficient for constant pressure, and

$$F(s) = \frac{2}{s\sqrt{-j}} \frac{J_1(s\sqrt{-j})}{J_0(s\sqrt{-j})} \quad (33)$$

where J is the Bessel function of the first type. To obtain an equivalent radius for the Kirchhoff model, the hydraulic radius has been used. For square narrow pipes ρ_p and c_p can be calculated according to Stinson.⁵⁶ Comparing the results with the previous values using the hydraulic diameter gives a difference less than 2%.

5.8.2 Diesel Particulate Filters The first acoustical model for diesel particulate filters was the one-dimensional model presented by Allam and Åbom.⁵⁵

Figure 19 Cross section of a unit cell in a DPF split into five sections — each described by an acoustical two-port. Note the filter section (II) is actually an acoustical four-port but can be reduced to a two-port due to the hard walls in sections I and III.

This model has been improved^{52,56} using an extended version of the model proposed by Dukomaci for catalytic converters.¹⁶ A brief summary of the models is given below. A cell in a diesel particulate filter (DPF) is shown in Fig. 19, which illustrates how the flow and acoustic waves are forced through the porous walls. As seen from this figure, the filter can be split into five sections: the inlet cross section (IN), a short narrow pipe with hard impermeable walls (I), the filter section consisting of narrow pipes with porous walls (II), a short narrow pipe with hard impermeable walls (III), and the outlet cross section (OUT). In the plane-wave range these sections can be described via two-port transfer matrices (T). The resulting transfer matrix for a filter unit is then simply given by

$$T_{\text{DPF}} = T_{\text{IN}} T_{\text{I}} T_{\text{II}} T_{\text{III}} T_{\text{OUT}} \quad (34)$$

The IN and OUT sections represent coupling two-ports associated with a sudden area change and are obtained by applying the principle of conservation of energy and momentum.⁵⁴ At room temperature this model must be modified since then there is turbulent channel flow in a part of the narrow channels. This creates a quadratic pressure drop that can be expressed as an equivalent acoustic resistance at the IN and OUT sections. This resistance can be represented as a lumped two-port element. Regarding sections I to III, they can either be represented using the one-dimensional model of Allam⁵⁴ and Keefe⁵⁷ or the model from Allam⁵⁴ and Allam and Åbom,^{57,58} which fully includes the viscothermal effects.

6 SOURCE DATA

As mentioned in Section 4.3 information about the properties of the engine as an acoustic source and the exhaust tailpipe opening as an acoustic load is needed for predicting the sound radiated from the exhaust. For predicting the insertion loss, the reflection properties of the source in the form of the source impedance is needed. In the following sections it is explained how source data can be obtained from experiments or from simulations using gas exchange codes. In some cases source data is not available, and some authors have suggested estimates based on experience from practical design of exhaust systems. Callow and Peat,⁵⁹ for example, suggested the frequency-independent source

impedance $Z_S = \rho_0 c \exp(i\pi/4)$, as a good estimate when source data information is not available.

In the review papers^{5,60,61} on the subject, source models applicable for different types of sources are discussed. For internal combustion engines it is usually sufficient to consider one-dimensional models for the sound propagation in the main exhaust pipes. The main question is whether a linear time-invariant source model can be used or if time variance and nonlinearity must be considered.

6.1 Linear Time-Invariant One-Port Source Models

If there is only one degree of freedom at the interface between a linear source and the system, a one-port source models can be used. For in-duct fluid-borne sound sources, this corresponds to cases where there is a plane wave state in the connected duct.

In the frequency domain an acoustical one-port can be completely described by a source strength (p^s or q^s) and a normalized source impedance (ζ_s):

$$p = p^s - Z_0 \zeta_s q \quad (35)$$

where p^s is the source pressure, p and q are acoustic pressure and volume velocity, respectively, and Z_0 is the characteristic impedance of the fluid. The volume velocity q is defined positive in the outward direction from the source, and all quantities are referred to a reference cross section. Describing the exhaust or intake system as a passive (i.e., source-free) linear and time-invariant duct system, the following relationship will also apply:

$$p = Z_0 \zeta_r q \quad (36)$$

where ζ_r is the normalized receiver or load impedance. The interaction between source and receiver is normally represented as an equivalent circuit as in Fig. 20.

6.2 Experimental Methods for Determining Acoustical One-Port Source Data

The measurement methods can be divided into direct or external source methods and indirect or multi-load

Figure 20 Representation of a fluid-borne sound one-port source as an equivalent circuit.

methods. The *direct* methods are two-step methods. First the passive source data is determined by exciting the source from an external source. The same type of methods used to measure the acoustic impedances or mobilities of passive systems can be used. In the second step the external source is turned off, and the source strength is determined by making a measurement when a known receiver load is applied to the source. One problem with this method is that in the first step when the external source is used only, the signal from this source and not the signal from the source under test must be picked up by the transducers. The problem can in principle be solved by increasing the level of the external source. This has been attempted for IC engines^{62,63} but did not succeed completely, and good results could not be obtained in the low-frequency region, where the engine produced the highest sound pressure levels. Another possibility is to use a reference signal correlated with the sound field from the external source, for example, an electrical signal exciting a loudspeaker, but not correlated with the sound field from the machine under test and by signal processing methods extracting the signal from the external source. Still sometimes it is difficult to find an external source that produces sufficiently high sound pressure levels. There may also be practical problems in mounting the external source in, for example, hot and “hostile” environments. This makes the indirect methods attractive for IC engine applications.

When using the *indirect* methods, the two unknowns—the source strength and the source impedance or mobility—are determined via a *multiload* procedure, that is, by applying known loads and measuring the sound pressure or the vibration velocity at the source receiver interface. Since there are two unknowns, two loads should be sufficient, which leads to the *two-load* method.^{64,65} If more than two loads are used, an overdetermined problem is obtained, which can be useful for improving the measurement results^{66,67} and for checking if the source behaves as a linear system.^{68,69} The two-load method applied to fluid-borne sound sources requires that it is possible to make complex pressure measurements, which means that a reference signal unaffected by acoustic load variations and related to the sound generating mechanism of the source is needed. For fluid machines with a periodic mode of operation the normal solution is to try to obtain a trig signal for each period. This procedure can catch the harmonic part of the spectrum generated by the machine but not the broadband part. It can also be noted that a trig signal always can be used to remove flow noise disturbances from measured pressure signals. An alternative method for flow noise suppression is to create a “noise-free” acoustic reference signal, by using one or several microphones with turbulence screens. Figure 21 shows an example of results from measurements on a six-cylinder truck diesel engine.

For situations where no suitable source reference is available, alternative methods have been developed where the autospectra of the pressures are measured

Figure 21 Effect of load variation on source strength, 1800 rpm, 100% load—full line; 50% load—dashed line; 25% load—dash-dot line.

instead of the complex pressures. The first such method was the *three-load* method.⁷⁰ By taking the squared magnitude of Eq. (36) one gets, after substituting, $q = p/Z_0\zeta_l$, a real-valued equation with three unknowns, that is, $G^s = |p^s|^2$ and the real and imaginary parts of ζ_s , $[\text{Re}(\zeta_s)$ and $\text{Im}(\zeta_s)]$. To determine the unknowns, one therefore needs to make measurements using three different loads. The resulting system of equations is nonlinear and can have more than one real-valued solution. This method is quite impractical to use and has also been reported to give large measurement errors. In the *four-load* method⁷¹ a fourth measurement is used to eliminate the nonlinear term containing $|\zeta_s|^2$. This method has also been reported to give large measurement errors. Bodén⁷² showed that the four-load method can be formulated as a linear system of equations, if the nonlinear term is interpreted as an independent unknown. By analyzing this formulation, it was concluded that the main reason for the previously reported measurement errors is the choice of loads. A new improved method for analyzing the same experimental data used for the four-load method was also presented.⁷² This method is based on a direct numerical fit of the data to the nonlinear model using least-squares methods. A comparison between the results obtained when applying the different measurement methods described above to various sources was also made. Based on this comparison it was concluded that (when it is possible to use them) the direct methods give the best results. A further improvement of the technique of Bodén⁷² has been presented by Jang and Ih.⁷³

6.3 Linear Time-Varying Source Models

When determining the passive acoustic data, that is, the source impedance of a fluid machine, it is assumed that it does not change with time. If the machine in action is studied, it is observed that pistons, valves, or fan blades move. One can, therefore, in principle

expect that even the passive acoustic properties should be time varying. In mathematical terms this means that the source is described by linear differential equations with time-varying coefficients. The time variation in the coefficients is normally caused by the periodic motion of the machine and will therefore be periodic. Using such a model for the machine, the problem can be solved either in the time domain or in the frequency domain. In the so-called Helmholtz resonator model, which has mainly been used for compressors,^{74,75} a set of linear differential equations with time-varying coefficients is derived and solved in the time domain by a Runge–Kutta method. A frequency-domain linear time-varying source model was developed by Wang^{76,77} for an internal combustion engine inlet system. By assuming that the variables and the coefficients have a periodic time dependence, so that they can be expanded in Fourier series, a frequency-domain model for the source can be deduced. Here the source strength is replaced by a vector containing the data for each frequency component, and the source impedance is replaced by a matrix that also describes the coupling between different frequency components that can occur at the source.

Bodén⁶⁶ and Bodén and Albertson⁷⁸ have presented measurement methods for determining the source data for such a model. The methods used are similar to the *multiload* methods used for time-invariant one-port sources. No major advantage of using these methods for applications on IC engines have, however, been found. The measurement methods have been applied to data from measurements on a compressor⁶⁶ and on the exhaust side of a truck diesel engine. Earlier measurements using the two-load method have indicated possible nonlinear engine source characteristics. Figure 22 shows the real part of the measured normalized source impedance for the truck engine. As can be noted the real part of the source impedance is negative for many frequencies, which is not physically correct for a linear source model. This could be an indication of nonlinear source behavior. Peat and Ih⁷⁹ have, however, shown that time variation

Figure 22 Real part of normalized source impedance. Engine speed 1200 rpm; three different engine loads.

alone can cause negative resistance values if a time-varying source is analyzed, assuming that it is time invariant.

6.4 Nonlinear Source Models

Many fluid machines such as compressors and IC engines are high-level acoustic sources. The validity of modeling them as linear time-invariant systems may, therefore, indeed be questioned. As discussed in the previous section, assuming a linear time-invariant source model when experimentally determining the source data frequently gives unphysical negative source resistance values. This has been interpreted as the effect of time variance and nonlinearity. The alternative is, of course, to use nonlinear models to describe the complete system; see, for example, Jones.⁸¹ Most works in this field have started from first principles, that is, the equations describing the conservation of energy, momentum, and mass in a fluid. To simplify the problem somewhat, lumped source models and one-dimensional sound propagation have normally been assumed. The resulting equations are solved in the time domain using the method of characteristics or finite difference methods. The disadvantage of using these methods, compared to the linear frequency-domain methods, is that they are more complicated and time consuming to use, and they cannot treat all the complicated geometries found in, for example, automobile silencers.

6.5 Linearity Tests

When using experimental methods to determine the source data of linear multiports, described in the previous sections, it is of interest to get a check of to what degree the source under test deviates from linearity and time invariance. For the one-port source a linearity test for direct methods has been proposed by Lavrentjev et al.⁶⁸ Further linearity tests for indirect or multiload methods were proposed by Bodén and Albertsson.⁶⁹ The idea behind the tests is to verify that the source data (p^s , Z_s) are unchanged under acoustic load variations.

6.6 Hybrid Linear/Nonlinear Source Models

The hybrid linear/nonlinear methods, where a nonlinear time-domain model is used for the source and a linear frequency-domain model is used for the receiving system, was first introduced for in-duct sources in Singh and Soedel⁷⁵ and Elson and Soedel.⁸¹ They used a frequency-domain iterative method to perform the coupling between the time-domain solution for the source and the frequency-domain description of the rest of the system. The same technique was also suggested by Jones⁷⁸ for application to IC engine exhaust systems and tested by Bodén⁶⁶ for a modified compressor with unstable results. The problem seems to be the chosen coupling technique, even though acceptable results were obtained.^{75,81} The harmonic balance technique is an alternative frequency-domain technique with better convergence properties. It has been used for microwave circuits in forced

oscillations and was adapted for modeling the self-sustained oscillations of woodwind instruments by Gilbert et al.⁸²

The hybrid methods can be divided into a number of main groups. One group is the iterative techniques, which can be further subdivided into frequency-domain iterative techniques^{75,81,83} and time-domain iterative techniques,⁸⁴ depending on which domain the convergence check and the coupling is performed. Another group is the convolution techniques where the frequency-domain impedance boundary condition is transformed into the time domain. The impedance boundary condition is given by

$$P(\omega) = Z(\omega)Q(\omega) \quad (37)$$

where $P(\omega)$ is the pressure at the boundary, $Z(\omega)$ is the impedance and $Q(\omega)$ is the flow velocity at the boundary. This equation can be transformed into the time domain giving

$$p(t) = \int_0^t z(t - \tau)q(\tau) d\tau \quad (38)$$

where $z(t - \tau)$ is the impulse response of the system with frequency response $Z(\omega)$. The convolution can be solved numerically, which can be rather time consuming. It has also been reported that the impulse response convolution technique can give unstable results. An alternative is to reformulate the boundary condition using the reflection coefficient R . The boundary condition is then given by

$$p^-(\omega) = R(\omega)p^+(\omega) \quad (39)$$

where $p^+(\omega)$ and $p^-(\omega)$ are the amplitude of the incident and reflected pressure waves at the boundary. The corresponding time-domain expression is given by

$$p^-(t) = \int_0^t r(t - \tau)p^+(\tau) d\tau \quad (40)$$

where $r(t)$ is the reflection function of the system with reflection coefficient $R(\omega)$. The reflection function seems to give more stable results. A reflection function convolution technique was used by Gazengel et al.,⁸⁵ as well as a number of other authors in musical acoustics, for time-domain simulation of single-reed wind instruments. An impulse response convolution technique was suggested in Gupta and Munjal⁸⁴ in conjunction with iteration. In some works on IC engine exhaust and inlet systems convolution using the reflection function^{86,87} or scattering matrix^{88,89} has been used. In these studies nonlinear wave propagation calculated using the method of characteristics, in the exhaust pipe upstream of the linear system boundary or even in between mufflers is an important part of the model.

7 LOAD DATA

The passive termination of the flow duct is, in general, more simple to model compared to the source, and at least in the case of negligible mean flow accurate theoretical models exists for the most common geometries. The effects of mean flow on flow duct terminations have been studied, both theoretically and experimentally, in a number of works. Due to the complexity of including an unstable vortex sheet, some discrepancies between the different works are found. Neglecting all effects of viscosity and heat conduction, the free-space termination has been rigorously treated by Levine and Schwinger in their classical work from 1948.⁹⁰ A good empirical fit to their results for the reflection coefficient \Re is obtained from⁹¹

$$\Re = -\Re_0 \exp(-ik2a\zeta) \quad (41)$$

where a is the tailpipe radius; \Re_0 and ζ are given by the following expressions;

$$\zeta = 0.6133 - 0.1168(ka)^2 \quad ka \leq 0.5$$

$$\zeta = 0.6393 - 0.1104 ka \quad 0.5 \leq ka \leq 2.0$$

$$\Re_0 = 1 + 0.01336 ka - 0.59079(ka)^2 + 0.33576(ka)^3 - 0.06432(ka)^4 \quad ka \leq 1.5$$

The load impedance may now be expressed as

$$Z_L = \rho_0 c \frac{1 + \Re}{1 - \Re} \quad (42)$$

A theoretical solution for sound radiation from a pipe with flow has been given by Munt.^{89,90}

8 AN APPLICATION

To illustrate the applicability of the linear frequency-domain analysis of a silencer for a small two-stroke IC engine with varying displacement is presented below. This analysis constitutes one step in the design of an improved silencer for a portable rock drill machine. Due to the complexity of the engine, it was not possible to obtain any reliable acoustic source data, and the analysis is restricted to transmission loss. This

Figure 23 Geometry and acoustical elements of the reactive rock drill silencer.

Figure 24 Calculated and measured (*) transmission loss for the rock drill silencer.

may seem as a major drawback, but the guidance given by this analysis is still useful in many practical design applications. As all measurements were made at room temperature and pressure (using a loudspeaker source), so are the simulations. The Mach number is at typical running conditions less than 0.05, and therefore all mean flow effects are neglected. The silencer is divided into acoustical elements as shown in Fig. 23 and specified in Table 1.

From these elements connected in cascade from inlet to outlet (elements 1 to 9), the transfer matrix and the corresponding transmission loss for the silencer have been generated. The transmission loss has also been measured using the two-microphone method and

Table 1 Type and Data for Elements Used to Model the Two-Stroke IC Engine Silencer^a

Element Number	Type	Data (cm, cm ²)	Comments
1	Straight pipe	$\ell = 3.5 + 1.1, S = 5.6$	*End correction from (71)
2	$\lambda/4$ resonator	$\ell = 3.6, S_r = 18.2, \Re = 1$	No yielding walls
3	Straight pipe	$\ell = 1.7, S = 18.2$	
4	$\lambda/4$ resonator	$\ell = 1.7, S_r = 15.7, \Re = 1$	
5	Straight pipe	$\ell = 4.6 + 2 \times 0.4, S = 2.5$	*End corrections from (71)
6	$\lambda/4$ resonator	$\ell = 3.4, S_r = 15.7, \Re = 1$	
7	Straight pipe	$\ell = 0.6, S = 18.2$	
8	$\lambda/4$ resonator	$\ell = 2.5, S_r = 15.7, \Re = 1$	
9	Straight pipe	$\ell = 10.6 + 0.4, S = 2.5$	*End correction from (71)

^a The length given for each element is the actual geometrical length, i.e., no end corrections apart from those specified are added

comparison between theory and experiments is thus possible.

As seen from Fig. 24 the agreement between calculated and measured transmission loss is reasonably good. The discrepancies that occur for higher frequencies are most likely due to near-field effects, which as seen from Table 1 either have been neglected or estimated from a similar geometry. Especially the effects in the region between elements 5 to 9, where the "flow" is reversed, are difficult to estimate. As the inlet and outlet to this region, that is, elements 5 and 9, are located eccentrically and on "opposite sides," the geometry is well suited to excite the first higher order mode of the main cross section, and increased accuracy thus requires three-dimensional analysis. Nevertheless, the simulation is still useful revealing the poor attenuation below 500 Hz, which, regarding the character of the exhaust noise emitted from most IC engines, shows that this prototype needs to be improved.

CHAPTER 86

TIRE/ROAD NOISE – GENERATION, MEASUREMENT, AND ABATEMENT

1 INTRODUCTION

The term *tire/road noise* denotes the noise emitted from a rolling tire as a result of the interaction between the tire and the road surface. In this chapter, only noise emitted outside the vehicle is considered; that is, *exterior tire/road noise*. In principle, not only the tire may radiate this type of noise; most notably structure-borne sound may spread to the rim and parts of the vehicle body and radiate from there, possibly also from part of the road surface, but radiation from the tire itself dominates.

A number of terms are used to describe this type of noise. For example, Americans currently tend to prefer *pavement–tire noise* or *tire–pavement noise*, and Germans tend to prefer *rolling noise* (*Rollgeräusch*). However, in this chapter the term *tire/road noise* is used since this was the term used in 1979 at an international conference and workshop where a particular working group addressed the terminology issue.¹

Exterior tire/road noise is one of the major environmental problems of modern society and one that is not stabilized or “under control.” Most other environmental problems where there are schemes, such as the Kyoto Protocol, intend to result in lowering or at least a status quo of future pollutions. Indications of the growing noise problem are social surveys and records of complaints to authorities. The substantial growth in traffic, especially in Europe and China, is another factor that suggests an increasing tire/road noise problem.

2 SIGNIFICANCE OF TIRE/ROAD NOISE EMISSION

Vehicle noise is composed mainly of tire/road noise and noise from the powering of the vehicle, what is here called *power unit noise*. Power unit noise, often also called *propulsion noise*, is composed of noise from the engine and all its accessories, the exhaust system and the transmission. Both tire/road and power unit noise have strong relationships with vehicle speed. Tire/road noise levels generally increase approximately logarithmically with speed (Fig. 1), which means that

on a logarithmic speed scale, noise levels increase linearly with speed. Power unit noise depends on a number of vehicle operating factors, most notably the gear selection and the engine speed, and its relation with vehicle speed is much more complicated than that of tire/road noise. At high speeds it follows almost the same noise–speed curve as tire/road noise, but at lower speeds it levels out at close to or somewhat above that of idling.

To simplify things very much, one can say that at low speeds power unit noise dominates while at high speeds tire/road noise dominates, and there is a certain *crossover speed* where the contributions are about the same. Figure 1 shows a rather typical example of vehicle noise from a modern car at various (but constant) speeds. Measuring conditions were similar to that of the International Organization for Standardization (ISO) 362² and ISO 13325.² Tire/road noise alone is represented by the curve labeled Coast-by. If one has two (incoherent) noise sources that are equally strong, the overall level will be 3 dB higher than the level for the single source, and one can then say that the power unit noise level equals tire/road noise level when the overall curve is 3 dB higher than tire/road noise. If it is less than 3 dB higher, tire/road noise will dominate. From Fig. 1 it follows that tire/road noise dominates over power unit noise for all speeds and gears except when driving in first gear. In practice, it means that at constant-speed driving tire/road noise always dominates.

Figure 1 is valid for only one passenger car, albeit rather typical for modern European, American, and Japanese cars. A more representative and general case, also including heavy vehicles, is shown in Fig. 2, which is based on data from the German model MOBILEV.³ The two parts of the figure show the contribution of tire/road noise to overall vehicle noise in an urban street and in a motorway situation. Since the figure is based on a model that has been developed from a huge amount of measurements, one may consider the results as representative of vehicles having “average” acoustic characteristics for north and middle European locations.

Figure 1 A-weighted vehicle sound pressure level SPL at constant speeds (cruise-by), as well as tire/road noise (coast-by) for a Volvo S40 (2000) in new condition. Cruise-by includes power unit and tire/road noise. Cruise-by levels for gears 3, 4, and 5 are very close to the coast-by curve and are therefore not shown. (From *Tyre/Road Noise Reference Book*.⁴)

The data in Fig. 2 may also be representative of Japanese conditions since Japan and Europe have equally stringent vehicle noise emission regulations. For North America and Australia, however, there are no corresponding data, but the authors' experience is that the heavy vehicles have noisier power units there; thus resulting in decreasing proportions of tire/road noise in these regions relative to the case shown in Fig. 2. In developing countries or in countries in transition, one may expect still higher power unit noise emissions leading to lower tire/road noise contributions.

3 TIRE/ROAD NOISE GENERATION

The generation mechanisms of tire/road noise have been explored since the 1970s. All this research has resulted in identification of an extremely complicated mix of mechanisms and related phenomena, all of which have been demonstrated to have some influence. The most influential mechanisms are listed in Table 1, which is the result of the authors' judgments based on the current status of research. There is generally no disagreement among most experts on the existence of these mechanisms and phenomena. However, the experts tend to dispute the relative importance of them.

There are some phenomena closely related to the generation mechanisms that influence the noise emitted to the roadside but that cannot be regarded as generation mechanisms. These are also included in the table, under Amplification or Reduction Mechanisms. Some of these are active immediately at the source, such as the pipe resonances, while others are active during propagation from the source to the far field, such as the horn effect and the sound absorption effect.

Tire/road noise generation mechanisms can be divided into two main groups according to the media in which they occur and their effects. One group is directly related to mechanical *vibrations* of the tire and are structure borne, as shown in Fig. 3. The other group is related to *aerodynamic* phenomena and are airborne and are pictured in Fig. 4. In the latter figure,

Figure 2 Share of total vehicle noise that comes from the tire/road interaction (white part of bars). The top figure is for an urban main street at a light-controlled intersection, posted speed 50 km/h, whereas the bottom figure is for a motorway with four lanes, posted speed 110 km/h, traffic volume (AADT) 50000. Data from a German study.³ (From *Tyre/Road Noise Reference Book*.⁴)

Table 1 Generation and Amplification Mechanisms of Tire/Road Noise

GENERATION MECHANISMS	
Structure Borne	
Impact mechanism (mostly radial vibrations)	<p>Tread impact: Impact of tire tread blocks or other pattern elements on road surfaces, causing radial and to some extent also tangential vibrations in the tire tread and belt, spreading to the sidewalls</p> <p>Texture impact: Impact of road surface texture on the tire tread, also causing radial and to some extent also tangential vibrations in the tire tread and belt, spreading to the sidewalls</p> <p>Running deflection of tire tread at leading and trailing edges, giving tire belt/carcass vibrations</p>
Adhesion mechanism (mostly tangential vibrations)	<p>Stick/slip tread element motions relative to the road surface, causing tangential tire vibrations, also called “scrubbing”</p> <p>Rubber-to-road stick/snap (adhesive effect); giving either tangential or radial vibrations</p>
Aerodynamical (airborne)	
Air displacement mechanisms	<p>Air turbulence: turbulence around tire due to the tire displacing air when rolling on the road, and air dragged around by the spinning tire–rim</p> <p>Air pumping: air displaced into/out of cavities in or between tire tread and road surface, without necessarily being in resonance</p>
AMPLIFICATION OR REDUCTION MECHANISMS	
Pipe resonances	Air displacement in grooves (“pipes”) in the tire tread pattern amplified by resonances, so-called $\lambda/2$ resonators
Helmholtz resonances	Air displacement into/out of connected air cavities in the tire tread pattern and the road surface amplified by resonances
Horn effect	The curved volume between the tire leading and trailing edges and the road surface constitute something similar to an exponential horn used to amplify sound
Acoustical impedance effect	Communicating voids in porous surfaces act like sound-absorbing material, affecting source strength
Mechanical impedance effect	Same, but affecting sound propagation to a far-field receiver
	The road surface gives more or less reaction to tire block impacts depending on dynamic tire/road stiffness proportions
	Some tire vibrations may be transferred to the road surface, possibly radiating as sound (speculation)
Tire resonance	<p>Belt resonances (mechanical resonances in the belt)</p> <p>Torus cavity resonance (resonance in the air column of the tire)</p>

also the *amplification* or *reduction* phenomena have been included since they are mostly (but not entirely) related to the aerodynamic mechanisms. These two figures are taken from the *Tyre/Road Noise Reference Book*.⁴

The various generation and amplification/reduction mechanisms are active or effective in different frequency ranges. There is no simple answer to the question of which mechanism is the most important, since their relative contributions vary for different tires, roads, and operating conditions. It must be stressed that for traffic noise impact considerations, not only generation mechanisms, but also the propagation of the sound from the source to the recipient is of great importance. More details on frequency ranges for the mechanisms and the relations between them are found in Ref. 4 or as further reading in various reports.^{5–7}

4 MODELING OF TIRE/ROAD NOISE

Several research institutes, universities, and R&D departments of tire and road manufacturers are developing models intended to describe and quantify the basic tire/road interaction mechanisms that lead to the

generation of noise. Probably, since it is more “handy” to work with car tires, these studies have so far mainly focused on passenger car tires. However, the noise generated by truck tires is often dominant and is expected to become increasingly important in the future, therefore requiring more emphasis on truck tire noise modeling in the near future.

The most frequently referenced model is probably the one produced at Chalmers University of Technology, Department of Applied Acoustics, Sweden. The structure of this model is shown in Fig. 5 as an illustration of all components needed in advanced modeling.

To review the various models, which in general are very advanced and complicated physical tools, in the limited space of this chapter is impossible. Instead, some references to models and modeling work are listed in the References.^{6,8–23} (this list is by no means complete, and we apologize for those not listed).

5 MEASUREMENT METHODS

5.1 Methods Mainly for the Study of Tires

A method developed for testing tires is specified in ISO 13325.² This specifies the so-called *coast-by method*

Figure 3 Vibration-related mechanisms of tire/road noise generation (tread impact and adhesion). (From the *Tyre/Road Noise Reference Book*.⁴)

Figure 4 Aerodynamically related generation (air displacement) and amplification mechanisms of tire/road noise. (From the *Tyre/Road Noise Reference Book*.⁴)

Figure 5 Tire/road noise simulation model developed at Chalmers University, Sweden. (Picture used with permission.)

for measuring tire/road noise; that is, a test vehicle is coasted past the microphone location with the engine switched-off. There is a microphone on each side of the vehicle (which often is simplified to only one side) at a 7.5-m distance from the center of the vehicle path and at 1.2 m above surface level. The illustration in Fig. 7 is applicable also to this method, although ideally one should measure on both sides of the test vehicle.

Laboratory drum facilities are often preferred for noise studies of tires; in cases where drum surfaces easily can be exchanged, the drums may also be used for pavement studies. In particular, drums are useful during the development phases of tires. In general, the test tire rolls on the rotating drum; but there are cases also when the drum is fixed and the tire is driven around the drum. Two such very different drum facilities are shown in Fig. 6. Furthermore, the test tire may be rotated either on the outer side of the drum or on its inner side. There is no standard method for drum measurements, but the setup of microphones in the close-proximity (CPX) method described in the next section is frequently

used. The two major concerns about the laboratory drum method are (1) representative drum surface and (2) drum curvature.

Earlier, drum facilities used a drum surface that was either just the plain steel surface or a sandpaper-like surface called “safety walk.” Such surfaces give noise emissions that are totally unrepresentative of actual roads. Nowadays, many facilities use surfaces that are made as replicas of actual pavements by use of molding techniques. In principle, one may have several such pavement replicas that can fairly rapidly be exchanged on the drum.

Studies of drum curvature influence on noise emission have indicated rather small or moderate effects. For car tires it seems that drum diameters down to 1.5 m are acceptable, for truck tires one would prefer at least 2.5 m.²⁴ In the United States most drum facilities use 3-m drums (10-ft diameter) in order to approximate the road geometry. Nevertheless, even meeting such requirements, there is little doubt that the curvature will influence noise to some degree,²⁵

Figure 6 Laboratory drum facilities at the Technical University of Gdansk (TUG) in Poland⁴ (top) and at the Institute for Safe, Quiet and Durable Highways (SQDH) in the United States (bottom). Only the top part of the TUG drum is visible above the floor. (Pictures used with permission.)

although it may be neglected in many cases in relation to other measurement errors.

5.2 Methods Mainly for the Study of Pavements

An ISO standard for measurement of pavement influence on traffic noise (ISO 11819-1)² was published in 1997. It is called the *Statistical Pass-by (SPB) method* and relies on a roadside measurement on a statistical selection of cars and heavy vehicles passing by the microphone (a minimum of 80 vehicles of each category). The measurements are processed in regression analysis of noise versus vehicle speed, from which an index called the Statistical Pass-By Index (SPBI) is determined, which is the characteristic vehicle sound pressure level for the particular pavement at a chosen reference speed. This method satisfies the type testing need above and is currently widely used. A revision with the aim to improve certain details in the method is underway. Figure 7 illustrates the SPB method.

To satisfy the needs of conformity of production (COP) tests and general surveys, work is underway in the ISO to standardize a measuring method for tire/road noise called the *close-proximity (CPX) method*, which was previously called “the trailer method.” Close proximity refers to the principle of the method that means that microphones (in this case two microphones) are positioned close to a test tire that is rolling over the pavement test section. Four test tires of different design have been defined in previous drafts, but this will be reduced to two tires in future drafts. The test tire is usually mounted on a trailer that is towed by a car or van, but the test tire may also be one of the normal four tires of a van or car. A committee draft, ISO/CD 11819-2, was accepted in 2000, and a new ISO draft is underway in which the CPX method is utilized for measurements comparing the noise characteristics of pavements. The CPX method is already widely used, essentially in Europe and the United States, but it is agreed within the ISO that it cannot replace the SPB method as the major method for classification of pavements; it is intended just for surveys and for tests of conformity of production. Figure 8 shows one example of a vehicle designed for CPX measurements according to the preliminary method worked out within the ISO. Many more devices are shown in the *Tyre/Road Noise Reference Book*.⁴

Measurements with the CPX method according to the ISO work are based on measurement of the sound pressure levels in the microphones. In United States, however, it is preferred by some to use an intensity probe (this also uses two microphones) and measure sound intensity rather than sound pressure.^{26,27} Sound intensity measurement is described in Chapter 45 of this handbook.

Sound intensity measurement has some advantages over sound pressure measurements, but there are also disadvantages, limitations, and problems. The setups used in the United States are usually similar to the example in Fig. 9. U.S. researchers have obtained excellent correlations between the sound intensity CPX measurements and cruise-by measurements on a test vehicle with similar tires.²⁷ Researchers are arguing about the pros and cons, but when this is written the sound intensity method is being developed into a possible national standard in the United States, whereas it has been rejected in Europe and on the international level due to its shortcomings.

The work to standardize the SPB and CPX methods has been and is being performed within ISO/TC 43/SC 1/WG 33, while the European Union (EU) project SILVIA further studied these methods and also provided detailed guidance on their use.²⁸

The ISO 13325² standard is sometimes also used for comparison of pavements. A variation of this is the so-called controlled pass-by (CPB) method, mostly practiced in France, in which a few special test vehicles and test tires are used as the measuring objects running at constant speed past the microphone on the pavements to be tested.

Many “low-noise” road pavements have significant sound absorption characteristics. ISO/TC 43/SC 1/WG

Figure 7 Typical setup for the SPB method, used at VTI. Recently the 2145 has been replaced with a B&K pulse system.⁴

Figure 8 Example of trailer used for measurements with the CPX method. This trailer is from the Technical University of Gdansk in Poland. For characterization of pavements, the method requires the use of two or four reference tires, which are used one at a time.⁴

38 is responsible for carrying out work on this, that is, for measurement of absorption characteristics in situ. One that is already worked out, ISO 13472-1,² is a free-field method, measuring a surface of a few square metres, with special signals emitted by a loudspeaker above the road and with microphone(s) picking up the signal for further advanced processing. Another method is being worked out with the intention to arrive at an in situ method with a better low-absorption resolution, utilizing a tube method, which measures the

absorption of a relatively small spot. These methods are mainly used for research and development so far.

Comparisons of the methods have been made.^{4,28} An international experiment to test the CPX method and compare several of the trailers in use today was conducted in the summer of 1998 in Europe.²⁹ In general, measurements conducted with the different methods may have a good correlation to each other if they are properly performed according to standards and

Figure 9 Typical setup for the sound intensity method.^{26,27} (Picture used with permission.)

“good practice.” On the other hand, if such concerns are not observed, correlation may be very poor.

6 LEGAL AND OTHER REQUIREMENTS

The only legal requirements with regard to noise from tires is Directive 2001/43/EC³⁰ of the European Union, amending Council Directive 92/23/EEC relating to tires for motor vehicles and their trailers and to their fitting. The directive requires new tires to meet the limits indicated in Table 2, which are illustrated for car tires in Fig. 10. The measuring method is the coast-by method similar to ISO 13325,² using a reference surface according to ISO 10844.² All measured and limit values are normalized to 80 km/h for cars and vans and for trucks to 70 km/h.

Table 2 Noise Emission Limits for New Tires in the EU^a Expressed as A-weighted Sound Pressure Levels

Type of Tire, Section Width (mm)	Limit Value (dB)	Limits after First Tightening	Limits after Second Tightening
For cars (C1)			
≤145	72	71	70
>145 ≤ 165	73	72	71
>165 ≤ 185	74	73	72
>185 ≤ 215	75	74	74
>215	76	75	75
Light trucks (C2)			
Normal	75		
Snow	77		
Special	78		
Heavy trucks (C3)			
Normal	76		
Snow	78		
Special	79		

^a Note that the values in the third and fourth columns are only indicative for tightenings in 2007–2009. Refer to the directive³⁰ for details. Final values will be decided after further studies have been made by the commission.

For car tires (class C1), the limits depend on tire section width; see Table 2. Reinforced tires are allowed *one* extra decibel and “special” tires (e.g., for off-road use) are allowed *two* extra decibels. For van or light truck tires (class C2), as well as for heavy truck tires (class C3), the limits do not depend on tire width but rather on the use of the tires: *normal*, *winter*, and *special*. Special tires are, for example, tires for use on trucks partly driven off-road, for example, trucks carrying building construction material, like gravel.

The broken lines in Fig. 10 show the *nominal* limit values, identical to those of Table 2. However, the measuring method requires that measured values be truncated, meaning that decimals are deleted. Furthermore, measured values shall be reduced by 1 dB. In practice, these two rules mean that a measured level of 75.9 will become 74 dB when a comparison with limits is to be made. It means that the effective limit in relation to what one measures is 1.9 dB higher than the nominal limit. The actual limits are therefore indicated in Fig. 10 as solid lines. Also shown in this figure are recently measured values, one point per tire. These data were measured in 2000–2004 by various organizations in Germany, Austria, Norway, and the Netherlands.^{31–35}

Figure 10 shows that the limits are substantially above the actually measured noise levels of current tires. Therefore, they are considered by all researchers to have no significant effect. Nevertheless, the EU Council of Ministers in the autumn of 2004 rejected a proposal to bring the limits down to levels where they would eliminate some tires.

In Japan, having no limits on tire noise, it has been considered to introduce the same limits as in Europe. However, a simulation study showed that the limit values are so high that they would not affect the Japanese traffic noise levels in any significant way. The EU limits were then rejected.³⁶

7 INFLUENCE OF TIRES

Figure 10 already gives a rough idea of how much noise levels between different tires differ, namely 6 dB in this selection. Data for a wider selection of car tires is presented in Fig. 11. This indicates a range of 10 dB between the best and the worst tire in a sample of nearly 100 tires of approximately similar sizes (the tires were all new or newly retreaded and available in tire shops). For truck tires, a study indicated a range of 10 dB between the best and the worst of 20 tires of similar size, measured on a surface that had similarities with an ISO surface, and 8 dB on another smooth surface.³⁷ Figure 10 indicates a difference between the worst and the best truck tires of 8 dB.

If one includes a large number of tires, one may get a range of about 10 dB, but when limiting the number to (say) less than 10, it is common to get a range of only 3 to 4 dB. In many cases, studies also concentrate on fairly similar tires. In addition to the ranges quoted above, one shall keep in mind that other variables like tire width and state of wear also affect noise levels and will increase the range further. When taking all such

Figure 10 Tire noise limits of European Directive 2001/43/EC,³⁰ as well as recently measured noise levels for tires. Car tires are in the top half (163 tires) and truck tires are in the bottom half (30 tires). (Data used with permission.)

Figure 11 Distribution of noise levels for a test sample of almost 100 tires.⁴ Measurement at 80 km/h with the CPX method on a dense asphalt concrete with a maximum aggregate size of 16 mm. The speed rating of the summer tires is indicated.

effects into account, it seems that the range for tires is approximately as large as for pavements.

In countries where people change from the normal summer to winter or to M + S tires in wintertime, most people expect that this leads to higher noise levels. The main reason is the “more aggressive” tire tread that winter tires need to have in order to carry away or penetrate slush and snow. The all-season tires are in an intermediate situation, with somewhat higher air–rubber ratio in the tread pattern. However, Fig. 11 shows that the winter tires are no longer noisier than the summer tires, except for a few types. The quietest tires are found in the winter group, and not even the average level is higher than for summer tires. If one would fit studs into the tread pattern, which is common

in Sweden, Norway, Finland, Iceland, Canada, and parts of Russia and United States, studs are generally increasing the noise emission by about 3 to 6 dB. It will then be possible to find certain studded winter tires that are less noisy than normal summer tires! The reasons are believed to be that winter tires generally have softer rubber compound than the summer tires and that their tread patterns are crossed by narrow sipes, giving a lamellae-like pattern—all making the tread block impact and footprint movements smoother. The tread patterns are also much more elaborate than in earlier times, not the least with the intention to reduce noise emission, and especially interior noise. However, traction tires that are intended for off-road operations usually have a hard tread compound that,

Figure 12 Tire/road noise level on various pavements, expressed as the CPXI measured with the CPX method, in this case using the TUG trailer of Fig. 8 at 80 km/h. Also indicated is the texture of each surface, expressed as mean profile depth (MPD) (see ISO 13473-1) and indicated by diamonds connected by solid lines.⁴

in combination with very distinctive block pattern, usually makes them noisy.

8 INFLUENCE OF PAVEMENTS

Large differences in tire/road noise emission have been measured on various pavements. See, for example, Fig. 12, which shows a range of 17 dB between the most "quiet" and the most "noisy" surfaces that have been measured. In Fig. 12 noise levels are expressed as levels of CPXI (close-proximity index) according to ISO/DIS 11819-2, measured with the TUG trailer.⁴ The CPXI is simply an average value of noise levels measured for the four reference tires provisionally used in this method. It seems to be an incredibly large range, but then one should not forget that the endpoints are indeed extreme surfaces. If one would limit the surface types to such that are safe surfaces for more general use, the range shrinks to 9 to 11 dB. The surfaces that are on the quiet side will probably also become less efficient after some wear, and the most noisy surfaces among the remaining would probably not be considered in a noise-sensitive situation.

The type of Portland cement concrete (PCC) surfaces widely used on U.S. high-volume roads, which are generally textured with transverse tines,

are not included in the sample of Fig. 12. However, comparing with measurements made in the United States,³⁷ the authors estimate that such pavements would fall in the range 101 to 104 on the scale of Fig. 12.

Figure 12 also indicates the texture of each surface represented by the mean profile depth (MPD) as measured with the ISO 13473-1² method. The diamonds connected with a line are the texture values, which relate to the scale on the right. The MPD has been found to be a good measure of surface texture for describing influence on wet friction and is increasingly used to characterize pavements. Note also that each bar contains a photo of its texture (common scale). It appears that the relation between the CPXI and MPD is far from clear; one can imagine a relation only when the surfaces are very rough.

In France, one can find a very comprehensive database on national pavement influence on tire/road noise; although there is one also in Germany. The French database is updated periodically and its most recent version is presented in Fig. 13. This version has been processed by the authors from data obtained from F. Besnard at SETRA.³⁹ The figure shows a compilation of a great number of measurements on

Table 3 Factors or Parameters Having a Major Influence on Tire/Road Noise

Speed of the vehicle	25 dB (increase from 30 to 130 km/h)
Pavement (incl. extremes)	17 dB (from the best porous asphalts to the worst stone setts)
Pavement (conventional)	11 dB (if stone setts are excluded)
Truck tire type (conventional, one size)	10 dB (same size; a couple of decibels more if different sizes are considered)
Car tire type (conventional)	10 dB (including width range 145–255 mm)
Car tire type (conventional)	8 dB (same width)
Studs in tire (relative to no studs)	8 dB (for new studs at low speeds; less at higher speeds)
Load and inflation	5 dB (for $\pm 25\%$ variation around nominal recommended values)
Road condition (wet/dry)	5 dB (increase in heavy rain; light rain gives lower influence)
Temperature	4 dB (over range 0–40°C; mostly decreasing noise with increasing temperature)
Torque on the wheel (normal driving)	3 dB (over range 0–3 m/s ² ; increasing noise with increasing acceleration)

Source: From Sandberg and Ejsmont.⁴

French roads on various sites in different conditions using the SPB method (ISO 11819-1).

Each group or column of data represents one major pavement category, and each point in it represents a measured pavement within this category. The individual points show the range of measured values for that particular pavement type, and the horizontal bar in the middle of each noise level distribution shows the arithmetic mean of all points. The noise differences appear to be 10 dB over the range of pavements if averages within each group are considered and 15 dB if individual values are considered. For the truck traffic, these ranges shrink to 5 and 10 dB, respectively.

9 OTHER PARAMETER INFLUENCE

The major factors or parameters that influence tire/road noise are listed in Table 3. The authors have attempted to list them in terms of their relative influence. Note that this is just a rough estimation since each factor is very much dependent on a number of conditions.

No other single factor has such a prominent influence on tire/road noise as speed. It is well known that the noise relationship with vehicle speed very closely follows the ideal relation:

$$L = A + B \log(V)$$

where L is the sound pressure level (SPL) in decibels, V is the speed in kilometres/hour, and A, B are speed coefficients (constants). The curve for coast-by in Fig. 1 is a good example of this. If this curve would be fitted into a diagram where speed scale is logarithmic instead of linear, the noise–speed curve will be essentially a straight line. However, on top of this basic relation, there is often a “fine structure”, at least if the pavement is smooth and the tire has a nonrandomized pattern.

10 COMMON SPECTRAL FEATURES AND THE “MULTICOINCIDENCE PEAK”

Frequency spectra may have very different shapes depending on the particular tire–pavement combination. However, Fig. 14 is an attempt to show some

common features. The figure contains spectra from a great number of cars and trucks cruising past the wayside microphone (7.5 m distance, 1.2 m height) and captured when the A-weighted level is at its maximum. The spectra are averages for each vehicle group collected by means of the SPB method. Spectra for two pavement types are shown: one stone mastic asphalt (SMA, maximum 16 mm chippings) having a “medium rough” texture, and one double-layer porous asphalt (DPAC, maximum 11 mm chippings in the top layer and 16 mm in the bottom layer, total thickness 80 mm). The SMA is the dominating type of pavement on Swedish highways, and the DPAC is a state-of-the-art noise-reducing pavement. Due to the averaging for all vehicles, the spectra are smoother than they would be for individual vehicles cruising by. There is also a small contribution of power unit noise at frequencies outside the range of 600 to 1200 Hz for trucks. If a more rough-textured surface would be tested, the levels at frequencies below about 800 Hz would increase significantly, while the levels above about 1000 Hz would decrease somewhat. If a smoother surface would be tested, the contrary effects would be recorded.

In Fig. 14 it can be seen that the light vehicles display a rather pronounced peak around 1000 Hz. Tire manufacturers nowadays employ very advanced methods to make sure that tread patterns are properly randomized, in order to avoid tonal components. It follows that tire/road noise spectra should show broadband characteristics. However, typical A-weighted frequency spectra often have a shape that contains a pronounced peak at around 800 to 1250 Hz; see Fig. 14 for an average fleet of cars but also Fig. 15, which is for individual tires. The measurements in Fig. 15 were made with the CPX method on a laboratory drum covered with a replica of an ISO 10844 surface. However, similar results were obtained on other fairly smooth surfaces and for CPX measurements made on trafficked roads. Narrow-band spectra do not reveal any special features in this case, so it is justified to say that randomization has been successful. However, one cannot really say that the 50 spectra are of broadband character, having one or two third-octave bands at 800 to 1250 Hz dominating the emission.

Figure 13 Comparison of A-weighted sound pressure levels measured in France with the SPB method on a great number of different pavements, classified into 11 categories.³⁹ The figure is based on data collected over many years. The top half contains data relevant to traffic by light vehicles (cars); the bottom half data is relevant to traffic by heavy trucks. Note: chps = chippings.

Figure 14 Third-octave band spectra for an average of about 100 heavy vehicles and about 150 light vehicles traveling at constant speed on two different pavements (see text); measured 2003 in Sweden with the SPB method.

Figure 15 A-weighted third-octave band spectra obtained for 50 different car tires running on a drum with an ISO replica road surface at a speed of 90 km/h.⁴⁰

The reason for this peak is the unfortunate coincidence of several generation, amplification, and propagation mechanisms, several of which happen to have prominent features around 1000 Hz; the so-called multi-coincidence peak.⁴⁰ These mechanisms are further identified and discussed in the reference. In addition, the peak corresponds with the frequency bands where the human hearing is sensitive.

11 LOW NOISE SOLUTIONS: TIRES

Figures 10 and 11 indicate that there are tires that are much quieter than the majority of tires. Some of them might be designated low-noise tires.⁴ The quietest tire in Fig. 10 is, for example, 8 dB less “noisy” than what the EU Directive allows. Evidently, there is a substantial potential for improvements just by selection of the quietest tires.

Low-noise solutions for tires may be sought in the principles applied to modern winter tires: soft rubber compounds, the extensive use of narrow sipes, not too wide tires. As far as possible one should attempt to reduce the multi-coincidence peak since this dominates the A-weighted overall level totally. Further, it is essential to design the tread in a way that optimizes the impact of tread elements on the pavement, by suitable directions and angles of the tread elements. Grooves that can create pipe resonances shall be designed for maximum “ventilation,” and they should not have a constant width or a well-defined length.⁴¹

The major tire development centers work on noise reduction for their tires, mainly because of requirements for interior noise and mainly due to pressure from the vehicle manufacturers. Some of this extensive work also has a positive influence on exterior noise.

Projects for development of quieter tires conducted and reported openly are not many. An example is a planned EU project SILENCE, which will have as one of its many activities related to road and rail traffic noise a work package aimed at development of a quieter tire. A second example is the recently

Figure 16 Prototype for a composite wheel. Note the slots in the tread band, which are providing ventilation to the grooves in the tread band.⁴

completed German Silent Traffic research program.⁴² However, no document on this matter seems to be available in English. Another example is a project run by the authors in which prototypes for a so-called composite wheel are developed in cooperation with its inventor H. E. Hansson.⁴³ One such prototype is seen in Fig. 16. The same principle was reported already in 1990 to give very low noise emission,⁴⁴ although the version of Fig. 16 has serious problems with frequencies generated by the periodic spoke impact. When this was written, Michelin had just launched its new “revolutionary” TWEEL construction,⁴⁵ which is a combined tire and wheel resembling the one in Fig. 16.

Another innovative design tested recently is the porous tread tire. This tire uses the carcass of a conventional tire but has a tread that is not cut into grooves, blocks, and other elements but is composed of rubber granules a few millimetres in size that are bound together with polyurethane and then form into a porous band.⁴⁶ See Fig. 17. This porous tread tire had, when this was written, been tested only partly, but current results indicate a noise emission that on both smooth- and rough-textured pavements was substantially lower than any pneumatic tire, including slick tires. Rolling resistance was comparable to the conventional tire, but wet skid resistance was poorer, the latter probably due to the use on nonoptimized rubber compounds (the rubber granules were produced from old scrap tires of various qualities).⁴⁶

12 LOW-NOISE SOLUTIONS: PAVEMENTS

A number of low-noise solutions for pavements have been proposed of which some are already implemented. The following is a list of such solutions:

Porous Pavements Asphalt or concrete pavements designed with a high proportion of air voids give a porous structure that absorbs some of the sound during

Figure 17 Two prototypes of the porous tread tire, produced by B. Kalman (VTI, Sweden) and A. R. Williams (UK, formerly at Dunlop Tyres).

its propagation and also reduces the aerodynamically related mechanisms at the source. The most effective design seems to be the double-layer porous asphalt, in which a top layer has rather small chippings to create a smooth surface to roll on and a bottom layer has much larger chippings, which will provide effective escape channels for water and air. The void content should exceed 20% in order to be effective. Total pavement thickness is usually 45 to 90 mm. Porous asphalt has a potential for reduction of vehicle noise (including tire/road noise) by 5 to 8 dB in new condition but the problem is the durability. Clogging of the porosities quickly reduces the acoustic durability and ravelling (loss of chippings) limit the technical durability in situations where substantial tangential tire/road forces occur. Modifying the binder with, for example, rubber may improve the performance in certain ways.

The DPAC pavement in Fig. 14 is an example of a very favorable one and shows the spectral effects achieved in such a case. The reductions are basically caused by a combination of (1) reduced air pumping due to excellent drainage, (2) reduced horn effect due to the lower horn surface being acoustically transparent, and (3) sound absorption during propagation to the receiver.

Porous asphalt pavements are rather widely applied already. For example, approximately 70% of the Dutch national highways are covered with porous asphalt, aiming at 100%. Most major expressways in Japan have porous asphalt as a wearing course. Recently, the use of porous asphalt has increased rapidly in large Japanese cities.

Optimized Texture In this case the megatexture is kept at a minimum and the macrotexture is aimed at providing drainage by using as small chippings as is consistent with requirements for appropriate wet skid resistance. The chippings may be rather small but they should provide a high degree of macrotexture in the texture wavelength range of 2 to 6 mm.⁴

Examples of such surfaces are surface dressings with dominating chipping sizes in the range of 2 to 6 mm. One proprietary surface dressing that is claimed to be suitable for low-noise solutions is the Italgrip pavement. Thin surfacings are usually thinner versions of dense asphalt concrete or stone mastic asphalt (SMA), which are easier to roll in order to obtain a flat top surface with plenty of voids in between. They usually provide some noise reduction, in general, based on texture optimization principles, since they are often based on rather small maximum chipping sizes and attempt to obtain an open structure. Thin surfacings have a potential for at least 4 dB of noise reduction compared to a dense asphalt or SMA with a maximum aggregate size of 16 mm.

Grinding; Exposing the Aggregate These are special treatments often applied to cement concrete pavements. Without special treatment, such pavements tend to have too low macrotexture, and to improve skid resistance increases in drainage are desirable. The old way of achieving this (still widely used in the United States but abandoned in Europe) is to provide laterally orientated grooves, so-called tining. Tining usually creates excessive tire/road noise; if the spacing is not properly randomized, it may even cause tonal noise components that are subjectively very objectionable and have given concrete pavements a bad reputation. A somewhat better way, with regard to traffic noise emission is to give the tines or grooves a longitudinal orientation. An alternative way to provide a suitable macrotexture is to grind the surface by a machine, so-called diamond grinding, which creates longitudinal narrow grooves but also a smooth surface. Another alternative way is to expose the aggregate, which is a technique to remove, during the cement curing process, the sand in the pavement surface, which then exposes the aggregate (the chippings). If the chippings thus exposed are small and closely packed together, such a pavement may get noise characteristics almost as good as the best (dense) asphalt pavements, which is also the case for the diamond ground pavements.

Asphalt Rubber Pavements In Arizona, to a smaller extent also in California and Texas, substantial amounts of very small rubber granules have been mixed into the binder of a pavement somewhat similar to an SMA, however, with much higher binder content than used in conventional mixes (up to 10% by weight). The term used in Arizona is asphalt rubber friction course (ARFC). ARFC pavements have a dense structure that somewhat resembles a texture-optimized surface and are also somewhat softer than conventional asphalt pavements and thus provide a softer impact between tire tread and pavement chippings. The authors believe that these properties combined contribute to the low-noise emission. According to recent measurements conducted both in the United States and Europe, the ARFC pavements in Arizona are almost as quiet as the European porous pavements⁴⁸ despite their generally somewhat denser structure.

Figure 18 Overview of test section with three types of poroelastic pavement (Rosehill, Tokai, Site construction), laid 2004 in Stockholm, Sweden, with a closeup view of the Rosehill surface texture on the right.⁴⁹

Poroelastic Pavements A poroelastic pavement is one that combines the porous structure with a soft aggregate. This is accomplished by adding substantial proportions of rubber particles into the mix. The most extreme pavement of this type is one that contains rubber particles bound with polyurethane and just minor additions of friction-increasing material such as sand or metal fibers. Such pavements often have a void content (by volume) of 30 to 40%. Sound reduction is achieved due to the porosity (see above) but also due to the softer impact between tire and pavement particles. Figure 18 shows an example of a field experiment with such pavements that took place in Stockholm in 2004. Measurements on three poroelastic pavement types showed tire/road noise reductions of 10 to 12 dB for normal tires and 13 to 15 dB for studded tires.⁴⁹ For a vehicle cruising by with the engine on, corresponding reductions were 6 to 8 dB. The Rosehill and Tokai types (see Fig.18) were prefabricated panels, the “site construction” was laid on-site with a small asphalt laying machine. Layer thickness was 30 mm. Similar field experiments with poroelastic pavements took place in Japan in 2002 and 2003 (but were interrupted in 2004).⁵⁰ This technique is not yet ready for full-scale application; further research is underway in Japan and Sweden.

Acknowledgments A number of illustrations and some data appearing in this chapter have been obtained from colleagues in other countries to whom the authors are grateful for their willingness to share their experience and results. It is acknowledged that the primary affiliation of the first author is the Swedish Road and Transport Research Institute (VTI), although this particular work was made within his secondary affiliation (Chalmers Institute of Technology).

CHAPTER 87

AERODYNAMIC SOUND SOURCES IN VEHICLES – PREDICTION AND CONTROL

Syed R. Ahmed

German Aerospace Research Establishment
Braunschweig, Germany

1 INTRODUCTION

In the unsteady flow around a moving vehicle, aerodynamic sound is generated at (a) abrupt changes in body geometry, (b) gaps in the body structure, (c) leaking or pliable seals, (d) appendages, and (e) interior heating, ventilation, and air-conditioning equipment (HVAC). Separated flow regions with fluctuating pressure exist at (a), (b), (d), and (e) and cause the radiation of sound. Leaking or vibrating seals and the flow from heating and air-conditioning systems also create interior noise. Structural vibration caused by the flow radiates sound into the air enclosed in the vehicle and to the surroundings.

Aerodynamic sound becomes significant at vehicle speeds above 130 km/h and increases approximately with the sixth power of speed. At speeds of 70 km/h and above, the aerodynamic sound becomes dominant in the frequency range of 330 to 900 Hz and remains so at higher speeds. At lower speeds, the tire/road interaction sound dominates in the vehicle interior. Interior sound affects the passengers' comfort level and has become the main focus for aeroacoustic optimization of vehicles.

The prediction and control of sound needs an interdisciplinary approach since fluid mechanics, structural mechanics, sound generation, propagation, and its structure-borne transmission are linked together. The exterior sound radiated and transmitted into the vehicle interior is a product of these coupled nonlinear mechanisms. Computational fluid dynamics (CFD) and computational aeroacoustic (CAA) methods addressing this problem are under development. Sophisticated testing techniques and experimental facilities are currently industrial tools widely used for the analysis and control of aerodynamic sound in vehicles.

2 IDEALIZED CONCEPTS OF SOUND SOURCES

Any sound source can be viewed as comprised of a distribution of (a) mass flow (monopole), (b) fluctuating pressure (dipole), and (c) fluctuating viscous force (quadrupole) sound sources. A monopole source is created by an unsteady volumetric addition or subtraction such as by the exhaust pipe or intake of a piston engine. It can also be generated by volumetric addition to the interior of a car through a leaking door seal. A dipole source is created by unsteady pressures acting on a rigid surface. A von Karman vortex impinging on a rigid body panel is such an example. A quadrupole

Figure 1 Sound pressure sensed by an observer from a moving sound source.

source develops due to a collision of two fluid elements as in a turbulent shear layer, creating fluctuating viscous forces in the flow.

For an observer on the ground (Fig. 1), a moving sound source produces a sound pressure p_a at location x and time t , given by

$$4\pi p_a(x, t) = \frac{\partial}{\partial t} \iint_S \left[\frac{\rho v_n}{r(1 - Ma_r)} \right]_{\text{ret}} dS + \frac{1}{c} \frac{\partial}{\partial t} \iint_S \left[\frac{P_r}{r(1 - Ma_r)} \right]_{\text{ret}} dS + \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \iiint_V \left[\frac{T_{rr}}{r(1 - Ma_r)} \right]_{\text{ret}} dV \quad (1)$$

where p_a = magnitude of air pressure fluctuation

ρ = air density

v_n = velocity normal to body surface

r = distance between observer and a point on body surface

$Ma_r = U_r/c$; Mach number of (body) velocity component U_r in direction of observer

dS = element of body surface S

c = speed of sound

P_r = component of pressure in direction of observer

T_{rr} = Lighthill tensor¹ (fluctuating viscous-stress tensor)

U = body velocity

dV = element of flow field volume V

The integrals on the right-hand side (rhs) of Eq. (1) are the monopole, dipole, and quadrupole source terms, respectively, which are to be evaluated at the

“retarded” time (subscript “ret”). This is the time t at which the sound signal is perceived by the observer minus the time needed for the signal to travel the distance between the body and the observer when the signal was emitted. The expression in Eq. (1) is usually known as the *acoustical analogy* associated with the name of Ffowcs Williams and Hawkins¹ (FWH analogy).

3 MONOPOLE, DIPOLE, AND QUADRUPOLE SOUND SOURCES AND THEIR DEPENDENCE ON SPEED, MACH NUMBER, AND FREQUENCY

The sound power (in watts) relationship of the individual sound sources is, after Chanaud and Muster,²

$$P_M \sim S_n^2 \text{Ma} \frac{Q^2}{(UL^2)^2} \rho U^3 L^2 \quad (2)$$

$$P_D \sim S_n^2 \text{Ma}^3 \frac{F^2}{(\rho U^2 L^2)^2} \rho U^3 L^2 \quad (3)$$

$$P_Q \sim S_n^4 \text{Ma}^5 \frac{T_{rr}^2}{(\rho U^2 L^3)^2} \rho U^3 L^2 \quad (4)$$

where P_M , P_D , P_Q = sound power of monopole, dipole, and quadrupole, respectively

$S_n = fL/U$ (Strouhal number)

$\text{Ma} = U/c$ (Mach number)

Q = fluctuating volumetric flow rate

F = fluctuating force (due to fluctuating pressure)

f = frequency

L = characteristic body length

From Eqs. (2), (3), and (4), an estimation of the relative importance of the sound sources can be made. With regard to *speed*, the sound power of the sources varies as

$$P_M : P_D : P_Q :: U^4 : U^6 : U^8 \quad (5)$$

With respect to *Mach number*, the ordering is

$$P_M : P_D : P_Q :: \text{Ma} : \text{Ma}^3 : \text{Ma}^5 \quad (6)$$

With regard to *frequency* the dependence is

$$P_M : P_D : P_Q :: f^2 : f^2 : f^4 \quad (7)$$

The efficiency of sound generation of a source depends upon the degree to which the fluctuations of mass (monopole), pressure (dipole), or viscous stresses (quadrupole) induce partially compressible fluctuations in the flow, which are then radiated to an observer as sound.

Experimental investigations of total sound radiated exterior to an automobile are indicative of monopole behavior for speeds below 120 km/h and dipole above it. The low Mach number speed range of ground vehicles

makes the quadrupole contribution insignificant, as seen from Eq. (6).

Since mass flow fluctuations are related to the overall size of the body, the monopole contribution to the frequency ($f = U/L$) for a body of 4 m length, moving at 140 km/h, would be in the range of 10 Hz. The length scale of the various separated flow regions on the body, which are the sources of the fluctuating pressures, is much smaller, say about $0.01L$, then the dipole contribution, which lies in the frequency range of about 1000 Hz. The quadrupole sound, which is intrinsically related to pressure fluctuations but scaled to eddy size, is important at the highest frequencies.

4 LOCATIONS OF AERODYNAMIC SOUND SOURCES ON VEHICLE BODY

The overriding consideration for ground vehicle body shape is dictated by the requirements of utility rather than aerodynamics or aeroacoustics. As noted in the introduction, at various locations on the vehicle body small or extensive flow separation regions exist with fluctuating pressure as shown in Fig. 2.

Type (a) locations (Fig. 2) are, for example, hood front edge, windshield base, windshield/front door transition (A-pillar), around recessed window panes, wheel wells, and the body underside. Multiple and extensive separated regions may be present between rear window and trunk lid (notch-back), and at the base of fast-back or hatch-back vehicles.

Type (b) locations (Fig. 2) are at structure gaps such as around doors, rain gutters, hood/windshield base, trunk lid, and the like. Type (c) locations (Fig. 2) are around doors, windows, trunk lid, sunroof, and the like. Type (d) locations (Fig. 2) are at external rear-view mirrors, windshield wipers, radio antenna, sunroof, popup head lamps, and the like. Type (e) locations are in the ducting and venting circuit of high-volume air-conditioning equipment.

5 FLOW DETAILS AND ACOUSTICS OF SOME TYPICAL VEHICLE BODY SOUND SOURCES

5.1 Flow at a Step Discontinuity

A backward- and forward-facing step can be present at a window pane and elsewhere. A backward facing step creates a pocket of separated flow, where the entrapped flow recirculates causing pressure fluctuations that increase dramatically in the vicinity of the flow attachment point as seen in the variation of the pressure coefficient C_p (Fig. 3).³

The effect of the flow disturbance can persist along distances over 50 times the step depth. The sound pressure level (SPL), for example, for 1 kHz frequency, may rise 20 dB above the level upstream of the step. Experimental results on a forward-facing step indicate a reduction of 4 to 5 dB for increasing the edge radius–step height ratio from 0 to 0.3, especially in the high-frequency range of 4 to 20 kHz (see Section 5.2).

5.2 Flow in a Cavity

Due to functional requirements, at various locations on the vehicle body gaps exist with a cavity underneath. The cavity air communicates with the external flow. Door,

Figure 2 Some locations of sound sources on an automobile body.

Figure 3 Flow details and acoustics of a step discontinuity.³

hood, and trunk lid slits, hood rear-edge/windshield base, rain gutters, open sunroof/window, and vehicle interior, are such examples. Flow of air over narrow cavities may produce high-frequency sound containing single or multiple discrete tones and in openings backed by a large volume, a low-frequency “wind throb.”

The boundary layer flow coming off the cavity upstream edge changes into a shear layer over the cavity mouth. This layer is inherently unstable and can oscillate. Its impingement on the cavity downstream-edge produces sound. Additionally, the fluctuating cross flow in the cavity mouth may produce sound. The downstream disturbances travel upstream, are enhanced at the cavity upstream edge and feed the shear layer oscillation. Rockwell and Naudascher⁴ categorized the oscillations as (a) fluid-dynamic, (b) fluid-resonant, and (c) fluid-elastic resonant. Type (a) oscillations occur due to instability of the shear layer. Resonant waves in the cavity air, by themselves or coupled to other phenomena, lead to type (b) oscillations. Fluid-elastic resonance oscillations [type (c)] are generated when the cavity air resonance is coupled to vibrations of the cavity surface. The intensity of the radiated sound depends upon how well the frequency of type (a) oscillation matches with that of resonance of type (b) and/or type (d) oscillation. A detailed discussion of cavity-flow oscillation mechanisms is given by J. Milbank.⁵

Rossiter⁶ found different modes occurring in fluid-resonant cavity oscillations. All predominant frequencies of cavity sound were found to lie close to the frequency bands of these modes. Work of Koch⁷ and others^{8,9} confirms this finding. Using Rossiter's semiempirical equation

$$\frac{K}{2\pi} = \text{Ma} \frac{c}{c_0} \frac{j - \gamma_R}{\frac{1}{K_R} + \text{Ma}} \quad (8)$$

where $K = \omega L / c_0$ (dimensionless frequency)

L = streamwise cavity length

$\omega = 2\pi f$ (circular frequency)

c, c_0 = local and ambient speed of sound

$j = 1, 2, 3, \dots$ (mode number)

γ_R = phase shift of acoustic scattering at cavity downstream edge

K_R = ratio of convective speed of the shear layer vortices to free stream velocity

the frequency of the modes can be estimated. Rossiter used the values 0.25 and 0.61 to 0.66 for γ_R and K_R , respectively.

For a cavity of $L = 0.5$ cm on a vehicle moving at 72 km/h, using Eq. (8) with $c = c_0 = 340$ m/s and $K_R = 0.61$, the resonance frequency for mode number 1 is about 1.8 kHz. As the human ear is very sensitive to frequencies around 1 to 5 kHz, this sound inside the vehicle can be very annoying. Door slits, uncovered holes, rain gutters, and the like etc. are thus sources of high-frequency sound.

At high speeds, the outer flow can induce sufficient forces on the door³ to deform or pull out the door

panels, causing leakage past the sealing or, if the flow is fluctuating, induce a similar response of the sealing, even if no leakage occurs. The flow mechanisms in the door slit, which can produce sound inside the vehicle, have been explained by Callister and George.¹⁰

Defective sealings and other sound leaking areas can be detected by placing an ultrasound emitter inside the vehicle and traversing the suspected outside area with a hand-held ultrasound receiver. The intensity of the received signal is a measure of the severity of the defect. Also a survey with a stethoscope inside the vehicle during wind tunnel or road tests is a simple means to detect air leaks.

Ethembaouglu¹¹ examined the sound attenuation by various geometries of the cavity downstream edge. A gradual slant or an elliptical edge was the most effective configuration.

Wheel wells are another location where a complex cavity flow is generated, which is mainly a source of external sound. Wind tunnel results for a full-scale vehicle (with stationary wheels) show sound with one-third octave center frequencies between 3150 and 6300 Hz close to the vehicle.³

Badger and Jones¹² modeled the “wind throb” due to an open window or sun roof and found the frequency of the oscillation is given by

$$f = \frac{c}{2\pi} \frac{\sqrt[4]{A}}{\sqrt{0.96V}} \quad (9)$$

with A the area of the opening and V the volume of the enclosure. For $A = 0.06$ m² and $V = 3$ m³, the oscillation frequency is about 16 Hz.

Since the natural frequency of the human head and eyes lies in the range of 15 to 20 Hz, this can be a source of serious discomfort and fatigue. Increasing the value of A raises the frequency at which the throb can occur and thus avoid it when the cruising speed remains the same.

5.3 A-Pillar Flow

The A-pillar flow is one of the most often investigated subjects both theoretically and experimentally. The airflow coming off laterally from the windshield separates as a sheath at the A-pillar and curls up into a conical vortex, much like the flow observed over a delta wing at incidence. The SPL values along a line aligned with vehicle motion and across the vortex, show a large increase in the vicinity of the flow reattachment on the side window pane—a location close to the driver's ear. The window glass pane being a poor sound insulator, the importance of this sound source is evident. The high SPL levels generated by the conical vortex are a consequence of its strong vorticity content. Due to safety considerations, the outside rear-view mirror is placed in the region of A-pillar flow, enhancing the sound generating flow on the window pane. Measures to inhibit the sound aim at matching the geometry of the A-pillar and the rear-view mirror to lower the vortex intensity of the flow.

The A-pillar curvature is an important parameter influencing the sound intensity. Large radii pillars are less sensitive to yaw-flow modulation of the interior sound. Sound modulation is an irritant, which lowers the comfort feeling inside the vehicle.¹³

5.4 Flow around Exterior Rear-View Mirror

The exterior rear-view mirror is an essential item to ensure driving safety and is placed in the viewing area of the driver, which is near the A-pillar vortex where high velocities exist. The mirror body may generate a closed bubble type of wake with recirculating flow inside or vortex shedding off its rim, depending upon minute geometry details. This flow may be partially or fully embedded in the A-pillar flow, creating a complex unsteady flow impinging on the side window. Wind tunnel results with a real car show an A-weighted SPL increase of 4 to 6 dB by a mirror over a one-third octave band of 1 to 10 kHz, inside the car. Small grooves and gaps in the rear-view mirror assembly are often sources of tonal sound. Tiny surface protuberances at suitable locations of mirror body help break up the periodic tone-generating flow.^{5,13}

The mirror body and attachment need a detailed matching with the local vehicle geometry. The goal thereby is to inhibit the pressure fluctuations, divert the flow away from or below the lower edge of the window pane and away from the driver's ear as well as decrease its vertical extent.³

5.5 Windshield Wipers

Windshield wipers whether in use or stationary are exposed to high velocities and the arm and wiper blade can generate significant amount of interior sound. Measures to reduce the sound focus on yaw-flow optimized geometry of the wiper arm and deflection of the airflow to above the wiper with an upward twist of the hood rear edge or placing the wiper below the edge to shield it from the airflow when stationary. Experimental results quoted in Helfer¹³ report a significant decrease in the SPL inside the vehicle over the frequency range of 1 to 10 kHz due to such measures.

5.6 Roof Racks

Roof racks are a common feature on SUVs and RVs and tonal sound from the rack crossbars can be a source of annoyance. The crossbars are exposed to the flow over the vehicle roof, and the periodic shedding of von Karman vortices from them produces a dipole-type tonal sound of a discrete frequency. With speeds above 70 km/h, this sound is readily heard inside the vehicle. A way out is the choice of a nonsymmetric cross section of the crossbar, which can significantly reduce the strength of the shed vortices without compromising the structural integrity needed for carrying the payload.¹⁴

5.7 Radio Antenna

The mechanism of “whistling” tones produced by a radio antenna is due to vortex shedding as mentioned for the roof rack. The use of a nonsymmetric cross section is unsuitable here as it affects the reception quality. The vortex shedding is actually three dimensional as depicted in Fig. 4.³ At one point the vortices are shed off the top (case A), and some distance away they are shed at the bottom (case B). Between these shedding nodes, there is an oscillating flow that moves along the axis of the cylinder. Since these flow mechanisms excite vibration of the thin and long antenna, the fluid dynamics and structural dynamics are coupled in the sound generation.

This tonal sound can be transmitted structure borne into the vehicle interior. A vibration absorbing fixture or tilted attachment of the antenna to the vehicle may reduce the sound to some extent but affects the radio reception. A helical strake of thin wire on the antenna rod can break up the intensity of the vortex shedding and sharply reduce the decibel level of the interior sound. Experimental results on a real car³ have shown an SPL reduction of about 15 dB at the original whistling frequency for a straked antenna.

5.8 Underbody Flow

Almost all vehicles have strongly structured undersides as exhaust pipes, mufflers, wheel axles, wheel cavities,

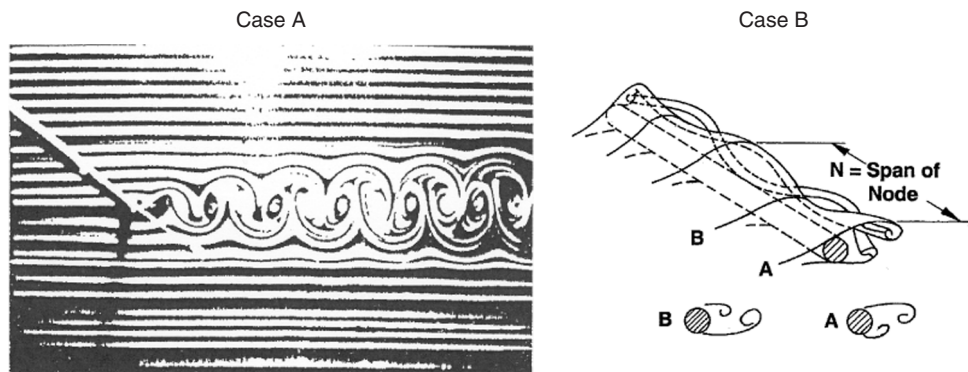

Figure 4 Vortex shedding off a long thin cylinder.³

and the like, are arranged on this surface. Most of the car engines are mounted in the front and the underside here is left open to improve the engine cooling. The air drawn in by the cooling fan in the engine compartment produces a complex turbulent flow that is fed into the gap flow between the underside and the road. This air flow interacts with the rough understructure and with the faster moving airflow along the sides. Since the vehicle body is elastically mounted on the wheels, its movement and road unevenness creates a time-varying ground clearance that translates into a time-dependent flow on the undersurface affecting also the global flow around the vehicle. The fluctuating pressures on the underbody are, due to its large plan form area, important for interior sound. The contribution is primarily of the low-frequency content. As is well known, the low-frequency sound is more difficult to insulate with floor carpeting. Wind tunnel results on a full-scale car with blocked underside flow show a typical reduction of about 2 to 5 dB at the driver's ear location³ in the A-weighted SPL for the one-third octave band of 50 to 150 Hz.

5.9 Rear-End Flow

At the rear end, all the characteristics of the upstream flow merge to form a complex time-dependent wake where viscosity effects dominate. Basically the wake coming off the blunt base is a time-dependent structure, containing low-frequency circulating regions with axes lateral and parallel to the vehicle base in an elliptical bubble (hatch-back vehicles) or longitudinal high-intensity vortices coming off the base slant of fast-back vehicles with a small wake bubble in the middle.³ The impinging of the fluctuating wake flow on the trunk lid and vehicle base is a source of interior sound. The large extent of the wake region leads essentially to low-frequency sound, which can be transmitted to the rear car interior. This can be readily observed with a slightly open trunk lid during driving. Reduction of vehicle drag through wake management in this area has often a beneficial effect on the sound generated.

6 SOURCES OF SOUND IN HVAC EQUIPMENT

A variety of components of the HVAC equipment contribute to the interior sound of the vehicle, which can be structure borne or aeroacoustic sound. HVAC sound is mainly of concern in the vehicle interior. It affects the comfort level, induces fatigue, and may, through distraction, lower the driving safety.

Components that generate aeroacoustic sound are the air ducts and vents, blower and the manifold. Sudden area changes, sharp bends, and other separation-prone details in the ducting lead to pockets of separated flow that are then the sound sources. Structure-borne sound is due to step motors, evaporator and heater, and the control unit. Details of the internal flow in these accessories as well as their mounting and location need to be examined in detail to inhibit their sound contributions.³

7 TEST FACILITIES FOR ROAD VEHICLE AEROACOUSTICS AND SOME ILLUSTRATIVE RESULTS

Aeroacoustic optimization of ground vehicles is mostly done in wind tunnels and to some extent with road tests. The tests are preferably performed at full scale, due to lack of a similarity law for sound such as exists for drag. Additionally, minute configuration details, which can be decisive sound sources, often cannot be duplicated on subscale models. The main advantage of wind tunnels is the controlled test conditions and the high accuracy of test techniques that ensure reproducible results. However, simulation of some real life situations like side winds, unbounded surrounding air, and the like are difficult or impossible to realize in a wind tunnel. Road tests are then the answer, but these are fraught with many uncertainties due to changing weather conditions and pavement qualities that are uncontrollable. This makes repeatability of the tests very difficult, and meaningful results can be obtained only from averaging a number of carefully selected test runs under consideration of the monitored weather conditions.

7.1 Aeroacoustic Wind Tunnels³

Automotive wind tunnels are normally equipped with either a $\frac{3}{4}$ -open, slotted, or closed test section. The $\frac{3}{4}$ -open jet closed-circuit configuration seems to be the preferred choice among European,^{3,13} Japanese,^{15,16} and newer tunnels in the United States.¹⁷ The open test section allows ease of access as well as efficient sound absorption of the plenum chamber where out-of-flow and far-field measurements can be made. However, the development of a shear layer around the jet and its impingement on the collector are sources of sound and flow oscillations (see Section 5.2) that can contaminate the sound measurements. As evident from Eq. (5), the sound power is strongly dependent on the vehicle speed. This means that during wind tunnel tests, the wind speed has to be maintained very precisely. Consequently, sound measurements are difficult to perform during road tests. The correct location of appendages on the body is also of prime importance as otherwise they may be exposed to a different velocity field.¹³

Aeroacoustic tests in the wind tunnel place stringent demands on the "background" SPLs in the test section. The purpose of the acoustical experiments is to simulate sound sources in the open atmosphere. The requirement is then that the background SPL in the empty test section should be significantly lower than level with the test object installed. An A-weighted SPL difference of about 10 dB over the frequency range of 50 to 8000 Hz is accepted as sufficient in the industrial practice. Another requirement is that the sound reflected by the tunnel walls should not contaminate the sound emitted by the test object. Ideally in such "anechoic" tunnels, the SPL decays at distances r larger than the wavelength λ , as $1/r$. This relationship—also called the *inverse square law*—governs the sound decay in the open atmosphere. Some details of

Figure 5 Background out-of-flow sound pressure levels of some aeroacoustic full-scale automotive wind tunnels.^{3,13,15–17}

the background sound suppression measures are available in the literature cited in Refs. 3 and 13.

A feeling for the out-of-flow background SPLs of some modern full-scale aeroacoustic automotive wind tunnels is gained from Fig. 5. The comparison of newer tunnels with the older Mercedes Benz (MB) tunnel (which is without an acoustical treatment) shows the improvement in the acoustics of the newer designs. The Audi tunnel in Germany achieves a decrease of almost 50 dB (A-weighted overall sound pressure level, OASPL) compared to the MB tunnel. The Hyundai and Ford DTF tunnels show values about 40 and 45 dB lower than the MB tunnel. The General Motors tunnel in the United States is about 10 dB quieter than MB tunnel; similar figures for DNW in Netherlands are about 15 dB, for Porsche slotted-wall tunnel in Germany and Volvo tunnel in Sweden, about 12.5 dB. The Volkswagen (acoustically untreated) tunnel is on par with the MB facility.

7.2 Some Aeroacoustic Measurement Techniques

A comprehensive overview of aeroacoustic measurement techniques used in ground vehicle work is available in Callister and George¹⁰ and Ahmed.³ Basically there are three different types of measurements

performed: (a) inside the vehicle, (b) outside the vehicle but inside the tunnel airflow, and (c) outside the vehicle and tunnel airflow. Each of these requires a different instrumentation and procedure.

7.2.1 Microphone Location Placing the data acquisition microphones outside the airflow increases the distance between the sound source and the data acquisition point reducing the *signal-to-background-sound* ratio. Also the sound signal, in an open-jet wind tunnel, has to cross the shear layer of the jet to reach the microphone. A refraction correction has then to be applied to the sound signal.¹⁸

Microphone placement inside the flow with supports makes them producers of sound besides the scattering effects on the sound to be measured. Hydrodynamic pressure fluctuations around the microphone body enhance the signal. Commercially available “nose cones,” slipped over the microphone head, alleviate the problem but are of little help when yaw flow conditions are encountered.

7.2.2 Acoustical Mirror This device, developed originally for aeronautical applications¹⁹ has found its way in a number of automotive tunnels. It is a convenient and robust system to directly identify the location and spatial distribution of the sound intensity of sound sources and is suitable for out-of-flow operation in open-jet wind tunnels.

Figure 6 illustrates the basic principle of this device. The concave mirror on the left is a segment of the ellipsoid of revolution indicated by the dashed line. The two focal points are the locations of a signal acquiring microphone and the sound source, respectively. Sound waves emitted by the source are focused on the microphone by reflection at the mirror, thereby greatly enhancing the signal sensed by the microphone. Since the measured SPL is directly related to the sound intensity of the source, the sound intensity distribution in a plane normal to the mirror axis can be surveyed by moving the mirror parallel to such a plane. Tests have shown that an elliptical mirror provides a better amplification than a spherical or a parabolic mirror.

For an efficient reflection of the sound waves, the wavelength λ of the oncoming sound waves should be small compared to the mirror diameter D , ($\lambda \ll D$). The frequency range of interest in automobile aeroacoustics is from about 50 to 8000 Hz. With $\lambda = c/f$ and $c = 340$ m/s, the corresponding wavelengths turn out to be 6.8 and 0.042 m. To capture the lowest frequencies, the mirror diameter becomes very large.

The amplification of the sound signal of a point source is shown in the inset of Fig. 6. The base width of this curve is a measure of the spatial resolution of the sound signal by the mirror. For the half width w the relationship is¹⁹

$$w \approx 0.54\lambda \left(\frac{S}{D} \right) \quad (10)$$

with S as the distance between the mirror base and the source. Choosing a value for S of 4 m, which is a

typical distance in a full-scale automotive wind tunnel test, and $D = 2.16$ m, one obtains for the half width

$$w \approx \lambda \quad (11)$$

The spatial resolution of a mirror of this diameter varies linearly with λ and would improve with higher values of the frequency. A mirror of this diameter is unwieldy, and smaller size mirrors are used in the industrial practice.

An example of exterior sound measurement on a real car with an acoustical mirror is presented in Fig. 7.¹³ The tests were conducted in a wind tunnel at a wind speed of about 140 km/h with the mirror placed 4 m away from the car. The OASPL results for the lower frequency range (0.5 to 4 kHz) show the front tire area and the trunk-mounted antenna as the major producers of sound. For the higher frequencies (4 to 9.5 kHz), the hood front, tires, rear-view mirror, and A-pillar area are the main sound contributors.

7.2.3 Spatial Transformation of Sound Fields (STSF)

The STSF technique enables the evaluation of the spatial sound field with near-field acoustical holography. The principle of this Fourier-transform-based technique is to measure the cross-correlated spectra of an array of "scan" microphones, which are traversed in a plane close to the vehicle (inset in Fig. 8¹³), and one or more fixed "reference" microphones.^{13,20} The cross-correlated spectra are determined for each scan-reference microphone combination as well as for reference microphones among themselves. Using Helmholtz's integral

Figure 6 Working principle of the acoustical mirror.

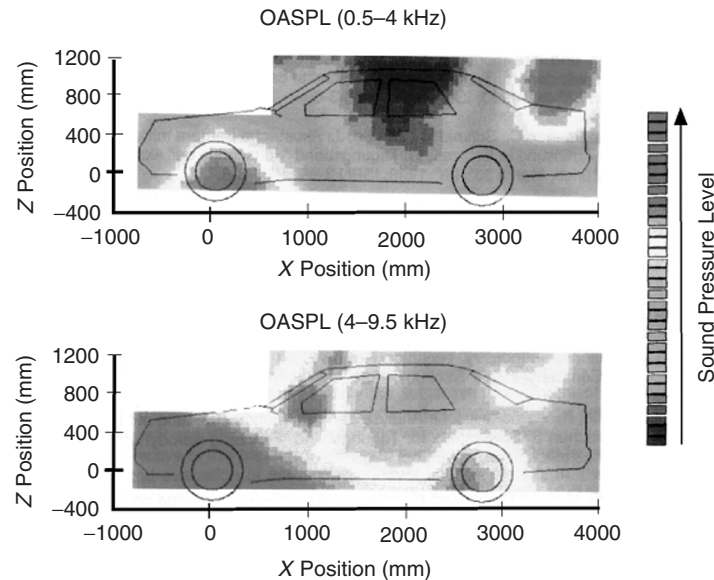

Figure 7 Measured sound pressure level map of a production car obtained with an acoustical mirror.¹³

relationship,²⁰ this data is used to determine SPL and sound intensity in other near- and far-field locations. The cross-correlation process eliminates mostly the self-induced signals of the array microphones through averaging so that the array microphones can be placed in the airflow. The location of the reference microphones is critical to the success of this approach, and exposure of these microphones to the airflow is to be avoided.

A result of this technique is shown in Fig. 8. The top right sound map shows some spurious sound sources in the rear-view mirror wake, when the traverse plane was too close to the vehicle surface. The elimination of microphone self-sound for this distance is incomplete. The lower maps, obtained at larger distances from the body are free of this error, exhibit somewhat lower SPLs.

7.2.4 Artificial Head Device The artificial head is a replica of the human head with microphones installed in the ear cavities. It is used for the *subjective* assessment of the spatial sound field in the vehicle interior. By hearing the recorded sound with headphones, a more realistic relative ranking of a set of different sample recordings can be obtained.²¹

7.2.5 Structure-Borne Sound Transmission To help identify sources of interior sound, the transmission paths of structure-borne sound need to be investigated. Often piezoelectric accelerometers are attached to the critical body parts to evaluate their vibration intensity and correlate with sound measurements inside the vehicle. The mass of the accelerometer has to be small so as not to alter the vibration characteristics of the part studied.¹³

A nonintrusive method for the purpose is the laser Doppler vibrometry.²² It is based on the principle of reflection of a laser beam from a vibrating body surface. The difference in the frequency of the incident and reflected beam is a measure of the vibration intensity at the point of reflection. This technique allows a rapid scan of vibration-prone surfaces.

8 PROBLEMS AND PROSPECTS OF COMPUTING SOUND GENERATION BY ROAD VEHICLES³

An analysis of airflow-induced sound involves, as mentioned in the introduction, the study of the unsteady flow field and flow-induced structural vibrations. This poses a formidable challenge to a purely theoretical approach. Ignoring the nonlinear coupling between the two, CFD and CAA may, in principle, be used to directly compute the sound generation and its propagation.

The flow around ground vehicles is for all practical purposes fully turbulent with Reynolds numbers (Re) around 7 to 8 million. It is adequately described by the unsteady Navier–Stokes (NS) equations. An overview of the CFD approaches to compute the ground vehicle flow was given by Ahmed.²³ The goal is to obtain the unsteady pressure distribution on the vehicle body or at least in areas of interest. The aeroacoustic part uses the fluctuating pressures, in a following step, to predict the sound with the help of some form of acoustical analogy such as given in Section 2.

Some problems that arise with a purely CFD-based sound analysis have been discussed by Hardin.²⁴ In brief these are:

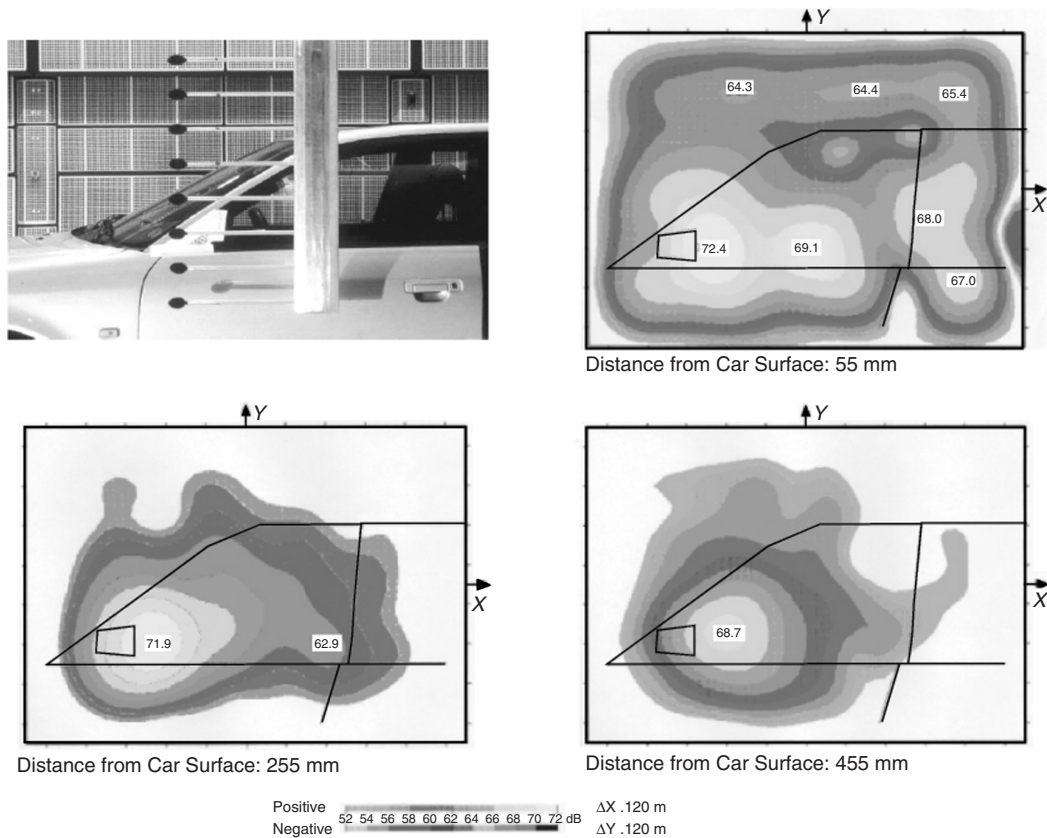

Figure 8 STSF scan-microphones and sound field map results.¹³

- The magnitude of the fluctuating pressures is of the order of 10^{-2} to 10^{-5} of the mean pressure. To capture such small values, the demands on accuracy become extreme.
- Numerical schemes affect amplitude “dissipation” and phase shift through “dispersion” in the propagating waves. High-frequency acoustic waves may thus be distorted.
- In CFD, grids are made dense in regions of interest and sparse elsewhere. For example, capturing the flow details in and around small cavities requires extreme fine grids. Such nonuniform grids can strongly distort the wave propagation.
- For exterior problems, the propagation domain is unbounded. A computation can be performed only over a finite domain. This raises the question of what boundary conditions are to be specified at the finite domain boundaries.
- The introduction of the time dimension dramatically increases the computational expense.

8.1 Some Computational Approaches

8.1.1 Lattice-Boltzmann Method (LBM) The method is of interest for vehicle aeroacoustics and offers an alternative to the conventional NS-equations-based CFD approaches. The principle underlying the method is briefly, as follows:

The movement of air is approximated as the movement of discrete air “particles” on a grid (lattice). Thus instead of the 10^{24} real-valued degrees of freedom of air molecules, a finite number of the degrees of freedom is allowed. As discussed by Rothmann and Zeleski,²⁵ the description of the motion need not be so detailed, yet it gives—in macroscopic sense—realistic fluid mechanic simulations.

The particles of the fictitious fluid move on a fixed lattice. Initially, the particles, each of unit mass, are located at the nodes of the lattice and possess equal velocities oriented along the lattice spokes. During a computation step, the particles hop to the next node, collide with other particles arriving at the same node and scatter along the lattice spokes according to a set of prescribed “collision rules.” The collisions cause the velocity and direction of movement of the particles to change, but neither the total number of

particles nor the vector sum of their velocities is changed. This means that the mass and momentum is conserved. Ensemble averages of the particle dynamic behavior lead asymptotically to the incompressible NS equations. Since the collision rules are framed to conserve mass, momentum, and energy of a particle ensemble after each computation step, the code mimics unsteady flow.

The time accurate computation of the unsteady aerodynamics makes the LBM method attractive for the computation of aeroacoustics using, for example, the unsteady pressure as input to the acoustical analogy-based codes. A commercial version of the LBM method, the PowerFLOW code, was used by Uchida and Okumura²⁶ to compute the sound generation on the front side window of a detailed vehicle model (Fig. 9). The simulation, done for a vehicle speed of 100 km/h on a 16-processor Origin 2000 workstation required 47 h of computer time.

Figure 9 gives an overview of the numerical model, the locations of the microphones on the window during the wind tunnel test, and a comparison of the computations with experiment. In general, the theoretical results show a higher SPL at the low and vice versa at high frequencies than the experiment. This example demonstrates the possibilities that may be available in future with more refinements of the code and denser grids.

For details of boundary element method (BEM) applications to sound radiation by a vibrating body, a cavity or the performance of mufflers, reference could be made to Seybert and Wu.²⁷

8.1.2 CAA Methods The CAA approach uses computational techniques to calculate all aspects of sound generation and propagation directly from the NS

equations.²⁸ Despite recent advances in prediction of sound with CAA, work of direct interest to vehicles is currently limited to simple basic geometries.

The low Mach number laminar boundary layer flow over a vehicle door cavity with a lip was investigated by Loh and Lin (see Ref. 28). They studied the influence of boundary layer thickness on the resonance modes, their frequency, and maximum SPL. Their results show the existence of more than three resonance modes (see Section 5.2) for both the thin and thick boundary layers. In both cases, the maximum SPL at a point above the cavity was due to the third mode. Kurbatski and Tam (see Ref. 28) (also considering a laminar flow over the same cavity) state that if the boundary layer becomes thick beyond a critical value, no tone is emitted.

8.1.3 Non-CFD Methods A number of sound estimation methods have been proposed in the literature based on *measured* fluctuating pressures at critical locations on the body and using this to predict the exterior or interior sound generation in a vehicle. The advantage of these methods is the inclusion of the structure–vibration contribution to the sound in the measured values.

Using the measured fluctuating pressure at various outside locations on the front side-window of a car, Haruna, Kamimoto, and Okamoto²⁹ isolate sound “sources” on the window pane by plotting pressure isobars for various frequencies. Each of these sound sources is accorded with a *correlation area*, which is obtained by observing the correlation behavior of the fluctuating pressure at the source and at points in the neighborhood. The contour passing through points with the highest correlation factor is the correlation area for the source. The source sound intensity I at a

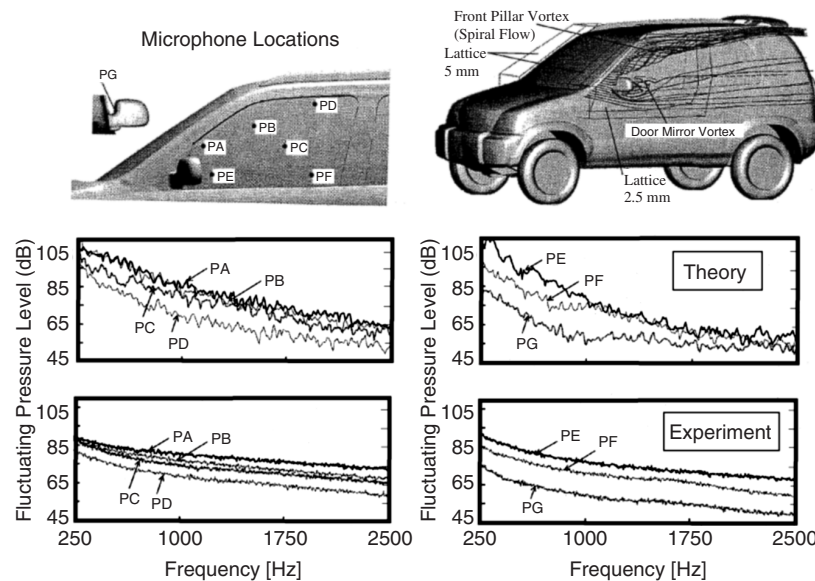

Figure 9 Sound generation on the front side window of a vehicle. Results of a computation with PowerFLOW code.²⁶

distance r , radiated from n sources is given by

$$I = \frac{1}{(4\pi)^2 \rho c^3} \left(\frac{\cos \Theta}{r} \right)^2 \sum_{i=1}^n (p_a f S_c)^2 \quad (12)$$

where Θ = angle between the surface normal at the source and r
 S_c = the correlation area.

Defining a standard intensity I_0 as

$$I_0 = \frac{1}{(4\pi)^2 \rho c^3} \left(\frac{\cos \Theta_0}{r_0} \right)^2 (p_{a0} f_0 S_{c0})^2 \quad (13)$$

where $\Theta_0 = 0^\circ$

$p_{a0} = 2 \times 10^{-5}$ (Pa)

$f_0 = 1$ kHz

$S_{c0} = 1$ m²

$r_0 = 1$ m

The SPL value is obtained as

$$\text{SPL} = 10 \log_{10} \frac{I}{I_0} \quad (14)$$

A result of this method is shown in Fig. 10 for the distance of 1 m for three different sets of frequencies over the speed range of 50 to 150 km/h. The SPL increases with the vehicle speed depending upon the frequency considered. For the lower frequencies (100 to 200 Hz) the exponent is 5.3, for the higher frequencies, it is 6.3.

An estimation method for the car interior sound has been developed by Dobrzynski.³⁰ The method uses the *measured* external fluctuating pressure and pressure

Figure 10 Estimated SPL from measured fluctuating pressure at side window of an automobile.²⁹

field correlation lengths to evaluate the SPL inside the car. The model simulates the pressure by a distribution

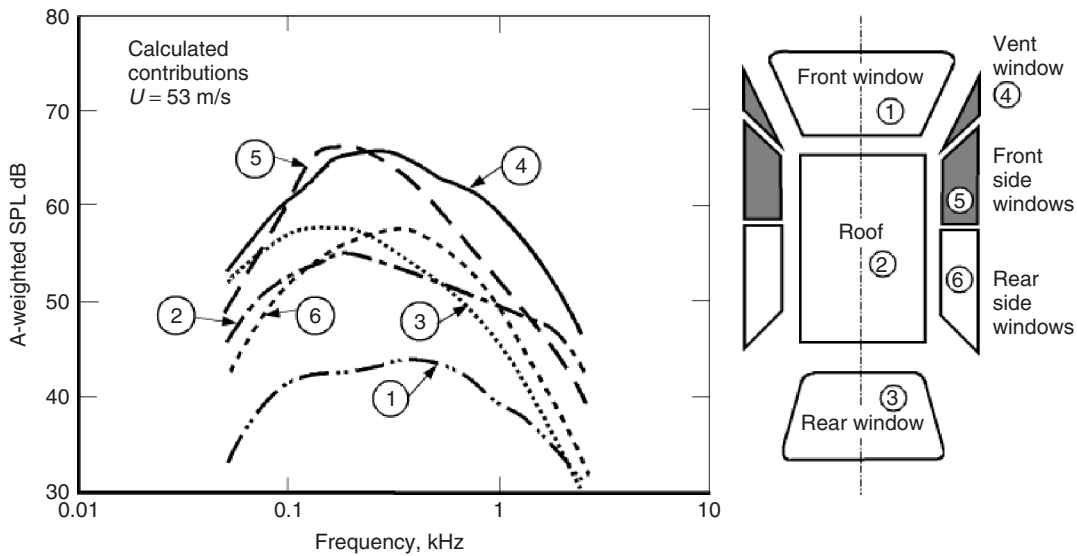

Figure 11 Estimated A-weighted sound pressure level contributions from different areas of the automobile body at driver's ear level.³⁰

of point forces acting on a homogenous panel. The forces produce bending waves in the panel that radiate acoustic energy. The obtained relationship states: The power of the sound generated is proportional to the root-mean-square (rms) value of the fluctuating force. The fluctuating force is the product of the pressure and a correlation area, which is an area in which the pressure fluctuations are in phase.

The intensity of surface pressure fluctuations (rms value) and correlation area are determined from experiment as a function of the frequency. The power of the radiated sound from any panel can then be obtained by adding the contributions of the correlation areas. To apply the method in a practical application, first all those locations on a vehicle body are identified that contribute significantly to the pressure fluctuations and evaluate there the fluctuating pressure intensity and the correlation quantities.

Figure 11 shows the estimated contributions from different areas of a fast-back-type full-scale car. The location considered is the driver's left ear of a right-hand drive car. As seen, the major contribution comes from the front vent and side window, which are engulfed in the A-pillar flow. The large area of the roof, which experiences low-intensity pressure fluctuations, is a comparatively weak contributor to the interior sound. The car rear, with a large flow separation, generates low-frequency sound perceived in the vehicle interior. The windshield turns out to be the lowest sound contributor of all the areas considered.

CHAPTER 88

TRANSMISSION AND GEARBOX NOISE AND VIBRATION PREDICTION AND CONTROL

Jiri Tuma

Faculty of Mechanical Engineering
Department of Control Systems and Instrumentation
VSB—Technical University of Ostrava
Ostrava, Czech Republic

1 INTRODUCTION

Except for severe bearing defects or extreme structure–resonance amplification, gears are the main sources of high-frequency vibration and noise, even in newly built transmission and gearbox systems. The gearbox overall noise level is usually no more than 5 dB above the noise level associated with the meshing gears. There are two possible solutions for reducing the noise of a transmission unit. Introducing an enclosure to reduce noise radiation is the easiest but creates maintenance difficulties. A more sophisticated and efficient solution involves tackling noise problem at the source. This requires improvements in gear design and manufacturing and results in the greatest reduction of noise. Vehicle transmission units are operated at many different loads and speeds. In designing low-noise transmission and gearbox systems, it is necessary to assess the noise and vibration sources and be aware of measurement methods, test procedures, and methods of diagnostics. Analysis tools for gearbox inspection are based on the frequency- and time-domain methods, including envelope and average tooth mesh analysis. To reduce noise radiated by transmission and gearbox systems, it is important to understand the effect of load, gear contact ratio, and tooth surface modification on noise and vibration.

2 DESCRIPTION OF TYPICAL VEHICLE GEARBOX AND TRANSMISSION SYSTEM

A typical two-stage car transmission unit arrangement with five forward manual gears and one reverse gear is shown in Fig. 1. It transmits power from the engine to the drive wheels, and it varies the amount of torque. There are actually two sets of gears in the drive train: the transmission and the differential. The transmission allows the gear ratio to be adjusted, and the differential lets the drive wheels turn at different speeds. The differential pinion, driven by the secondary shaft, turns the ring gear, which acts like a single-speed transmission reducing revolutions/minute (rpm) and increasing torque by a set ratio. Figure 2 shows two gear trains under load with the others free running.

Two single-gear trains transferring power from the input shaft to an additional countershaft divide up all the basic gears of the truck transmission unit. The gearbox output power is transferred to the axles via

Figure 1 Kinematic scheme of the car gearbox.

Figure 2 Fourth-gear train under load.

a drop gearbox working either at a fix gear ratio or at two gear ratios in the case that the drop gearbox is a planetary gearbox.

3 SOURCES OF GEARBOX NOISE AND VIBRATION

Gearbox noise is tonal. It means the noise frequency spectrum consists of sinusoidal components at discrete frequencies with low-level random background noise. The frequency that is the product of the gear rotational speed in hertz and the number of teeth are referred to as the base tooth-meshing frequency. A simple gear

train (a pair of meshing gears extended optionally by idler gears) is characterized by only one tooth-meshing frequency. All the basic spectrum components are usually broken down into a combination of the following effects:

- Low harmonics of the shaft speed originating from unbalance, misalignments, a bent shaft, and resulting in low-frequency vibration, therefore without influence on the gearbox noise level.
- Harmonics of the base tooth-meshing frequency and their sidebands due to the modulation effects, which are very audible; the noise and vibration of the geared axis systems is originating from parametric self-excitation due to the time variation of tooth-contact stiffness in the mesh cycle, the inaccuracy of gears in mesh, and nonuniform load and rotational speed.
- Ghost (or strange) components due to the errors in the teeth of the index wheel of the gear-cutting machine, especially gear-grinding machines employing the continuous shift grinding method that results in high-frequency noise due to the large number of the index wheel teeth; these ghost components obviously disappear after running.
- Components originating from faults in rolling-element bearings usually of the low-level noise except for severe bearing defects as the cracking or pitting of the inner or outer race or of the rolling element itself.

The frequency of the components, which are associated with the meshing gears, is an integer multiple of the shaft rotational frequency. There are subharmonic components as well. These components are excited at the half of the teeth resonant frequency in high-speed units (thousands of rpm) due to the nonlinearity of tooth stiffness. Other subharmonics originate from the rate at which the same two gear

teeth mesh together¹ (hunting tooth frequency). All these spectrum components are designated as orders of the shaft rotational frequency.

4 PASS-BY VEHICLE NOISE TESTS AND SIMULATIONS

The pass-by noise test requires the vehicle to be driven through a test site at full acceleration according to the International Organization for Standardization (ISO) 362:1994 Acoustic-Measurement of Noise Emitted by Accelerating Road Vehicles—Engineering Methods standard or the appropriate U.S. standards, namely the Society of Automotive Engineers (SAE) J-1470, SAE J-366, and SAE J-986. The A-weighted peak noise level at time constant FAST, measured in the decibel scale at a distance of 7.5 m (ISO) or 15 m (SAE) from the center of the test track. To analyze contributions of each individual simple gear train to the overall noise level, it is preferable to measure the time history of acoustic pressure and engine rpm during the pass-by test, as shown in Fig. 3. In contrast to a measurement with a stationary vehicle, during a pass-by noise test, the effect of the relative speed of the noise source and microphones is translated into the Doppler phenomenon and causes a positive (approaching) or negative (receding) frequency shift (typically from 2 to 5%) in the signals received by the microphones. As the Doppler frequency shift can lead to considerable errors for order tracking using a narrow-band pass filter, the noise source relative velocity to the stationary microphone must be evaluated using the instantaneous position and velocity of the vehicle on the test track.

Both these quantities can be either measured employing a radar system or estimated on the base of the engine rpm and the transmission unit gear ratio, including a mathematical model of the tire slip as a function of the longitudinal and normal force acting on the tire by the road surface.²

A noise multispectrum can be used as the input data for order tracking controlled by the frequency of receiving sound waves. A more suitable technique can

Figure 3 Pass-by vehicle noise measurements.

Figure 4 A-weighted noise level of the 27-tooth gear vs. vehicle position on test track.

be based on the Vold–Kalman order-tracking filter.³ An example dealing with the noise level of the first three harmonic components, which are excited by the 27-tooth gear, as a function of the vehicle position on the test track, is shown in Fig. 4. The filter bandwidth is required to be equal to 0.1 order of the engine rotational speed to reach the high selectivity of the noise signal analysis. The bandwidth of the bandpass filter in percentage to the basic frequency is equal to $0.1/27 \times 100\% = 0.37\%$, while the bandwidth for the second-harmonic component is equal to half of 0.37%, that is, equal to 0.18%. Both of the bandwidths are very narrow in comparison to the extreme value of the frequency shift due to the Doppler effect, which is equal to 1% for trucks.

5 TEST STANDS

The operating conditions of gears can be simulated using test stands to drive the gearbox in a similar way as during the pass-by noise test. Two possible solutions of the test stand arrangements are shown in Fig. 5.

In contrast to the open-loop test stand, the back-to-back test rig configuration saves drive energy. The torque to be transmitted by the gearbox is induced by a planetary gearbox. The gearbox under testing is enclosed in a semianechoic room. The quality of the semianechoic room is of great importance for the reliability of the results. The reverberation time should be less than is required in the frequency range at least from 200 Hz to 3 kHz. The input shaft speed is slowly increased from a minimal to maximal rpm, while the gearbox is under a load corresponding to full vehicle “acceleration”. To simulate the gearbox operational condition during deceleration, the noise test continues slowly decreasing from a maximal to minimal rpm.

Noise is usually measured by microphones located by the side of the gearbox under testing at the certain distance. One or two microphones can carry out measurements. Accelerometers attached on the surface of the gearbox housing near the shaft bearings can extend information about the noise sources. A tacho probe, generating a string of pulses, is usually employed to measure the gearbox primary shaft rotational speed.

Back-to-back test rig

Open loop test stand

Figure 5 Test stand arrangements.

6 FREQUENCY-DOMAIN ANALYSIS

The basic tool for signal processing in diagnostics is the Fourier transform (FT) of signals. The base frequency of all the exciting forces is related to the gearbox shaft rotation frequency. The gearbox is tested during steady-state rotation or run-up/coast-down. Clear information about the origin of extensive vibrations cannot be given by a single-frequency spectrum. Extensive vibration is excited when the tooth-meshing frequency or its harmonics meet the structural resonance frequency of the gearbox structure. It should be mentioned that any driven unit does not rotate at a purely constant speed, but its speed slowly varies around an average value. Spectrum components of the diagnostic signal result from the simultaneous, amplitude and phase modulation of the so-called carrying harmonic components that correspond to the excitation at a purely steady-state rotation. An amplitude modulation

of harmonic signals arises from the nonuniform periodic load, while a phase modulation is due to nonuniform rotational speed. Rotational speed variations at fixed signal-sampling frequency cause the smearing of the dominating components in the frequency spectra.

An analysis of signals from machines running in cyclic fashion is preferred in terms of order spectra rather than frequency spectra. The order spectra are evaluated using the Fourier transform of time records that are measured in dimensionless revolutions rather than seconds, and the corresponding spectrum components are associated with dimensionless orders rather than frequency in hertz. This technique is called order analysis or tracking analysis, as the rotation frequency is being tracked and used for analysis. The resolution of the order spectrum is equal to the reciprocal value of the revolution number per record, which is an input data vector of the length, equal to a power of 2, for the fast Fourier transform (FFT).

The signal-noise ratio is improved by averaging in both the frequency and time domains. Signal

resampling to the fix sample number per revolution is employed to eliminate the phase modulation effect at a tacho pulse frequency.

An example of gearbox noise spectra in decibels (Hanning time window and acoustic weighting of the A-type) during the runup test under load is shown in Fig. 6. The input shaft rotational speed was slowly increased from 1800 to 3500 rpm. As the rotational speed is increased roughly proportionally to the elapsed time, the three-dimensional spectral map illustrates how the various harmonics fall along radial lines and can thus be separated from the constant-frequency components due to excessive amplification by a structural resonance. The three-dimensional plot of noise order spectra in the form of a spectral map with the rotational speed in RPM as the third axis is shown in Fig. 7. Acoustical weighting of the A-type and the rectangular time window are employed. The constant-frequency components show up on hyperbolic curves in the number of rotations—harmonic order plane. The example in Fig. 7 corresponds to the gearbox described

Figure 6 Running noise autospectra in rms (waterfall).

Figure 7 Running noise autospectra in rms (spectral map).

by Figs. 1 and 2. The 40th harmonic, or in other words the 40th order of the input shaft rotational speed as the 40-tooth tooth-meshing frequency, dominates running autospectra in Fig. 7. The first five harmonics of the tooth-meshing frequency are usually sufficient to set up the frequency range for measurements.

The dependence of the overall noise level in decibels and the levels of the 40-tooth gear tooth-meshing frequency harmonics on the input shaft rotational speed is shown in Fig. 8. The curve in this diagram, designated by Sum, is a sum of the power contributions of the 40, 80, and 120 order components resulting in a noise level excited only by the pair of the 40-tooth and 39-tooth gears. As the pass-by vehicle noise test is based on the determination of the maximum of the overall noise level, the maximum of the gearbox overall noise level (Total) and the maximum of the noise level of each individual gear pairs can be chosen as a gear quality criterion. Because of the low tooth-meshing frequency of the 18-tooth gear, the maximum of the overall noise level exceeds the maximum of the 40-tooth gear noise level only by 2 dB. Almost only the meshing-gear pair contributes significantly to the overall gearbox noise level at its maximum.

Gearbox shafts are running coherently, therefore, it is possible to use the above-mentioned order analysis technique. On the other hand, the orders of noncoherently running systems, for instance, a gearbox during gearshift, with close or crossing orders can be extracted by the Vold-Kalman order tracking. The standard method based on the Fourier transform enables only speed-limited order tracking, while the Vold-Kalman order-tracking filtering is without slew rate limitation.³

7 TIME-DOMAIN ANALYSIS BASED ON SYNCHRONOUS AVERAGING

To study the excitation at each gear mesh cycle, the time-domain analysis based on synchronous time-domain averaging is more suitable than the frequency-domain analysis. This technique is also known as a

Figure 8 Overall A-weighted noise level (total) and level of the 40th, 80th, and 120th harmonic components vs. input.

signal enhancement, which has been treated by many authors, for example, McFadden⁴ and Angelo.⁵ This technique can be regarded as a “magnifying glass” (Angelo), whereby one can “focus” on the shaft to be examined. Noise and vibration signals are sampled using a tracking technique in such a way that the length of the time record is equal to the time interval of a gear revolution. Time records are triggered synchronously with a shaft rotation, and all the records contain the same number of samples (equal to a power of 2). The time-domain averaging of the samples on the same position in all the records results in a comb filtering with center frequencies coinciding with the integer multiples of the rotational frequency. The frequency response function of synchronous averaging is discussed in the Chapter 46.

Averaging in the time domain results in the reduction of the root mean square (rms) of an uncorrelated random signal, which is an obvious part of measured signals, that is, proportional to the reciprocal of the square root of the average number. For instance, if the averaging number equals to 100, then the rms of random signals is reduced by 20 dB. The responses of the gears, whose rotational frequency is a fractional multiple of the trigger frequency, and rolling bearings (fractional order of the rotational speed) are considerably attenuated as well. Except for timing gears, an ideal set of gears for even wear on each tooth does not have a tooth number with a common factor other than unity, which results in the mentioned fractional multiple.

8 AVERAGE TOOTH MESH AND ENVELOPE ANALYSIS

The averaged time records corresponding to a gear rotation are corrupted by modulation signals, which are in correlation with gear geometry errors or varying gear load. The modulation signals give rise to sidebands around the carrying components with a frequency that is corresponding to the harmonics of the tooth-meshing frequency. If all the spectrum components, except harmonics of the tooth-meshing frequency, are removed, then the purely periodic tooth-mesh waveform without the modulation effects is obtained. In view of this, the shape of this function may be illustrated by only one period corresponding to the time interval of one circular pitch rotation. In this way filtered signals (second averaging) are called average tooth-mesh signals.⁶ The average tooth-mesh acceleration measured on the gearbox housing close to the shaft bearing is proportional to the dynamic forces acting between the teeth in mesh.

An example of the gearbox acceleration signal averaging in the time domain is shown in Fig. 9. This figure contains the individual gear responses produced by each gear in mesh of the 40-tooth and 39-tooth gear pair under load (see Fig. 2). The response of the 40-tooth gear corresponds to the result of averaging, while the response of the 39-tooth gear is necessary to separate from the response of the 18-tooth gear (see Fig. 10) rotating at the same speed. Both these gears on the gearbox secondary shaft are under load.

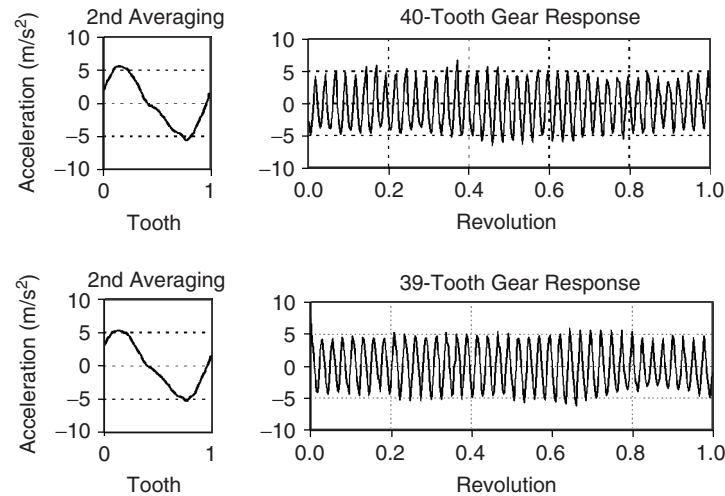

Figure 9 Acceleration responses of the 40- and 39-tooth gear train, envelopes, and averaged tooth-mesh signals.

An efficient way to separate both the responses is the transformation of the time record into the frequency domain using FFT. After putting some spectrum components to zero (the 18 order harmonics with their sidebands), the “frequency” signal is transformed back to the time domain using an inverse FFT; see Fig. 10.

It can be noticed that both the average tooth-mesh signals corresponding to meshing gears have the same shape. This fact follows from Newton’s third law. To assess a uniformity of tooth meshing during a complete gear rotation, an envelope analysis can be employed. The theory of analytic signals and the

Hilbert transform is a tool for envelope detecting. In contrast to the similarity of the averaged tooth-mesh signals, the envelopes of signals generated by meshing gears may differ from each other.

9 CEPSTRUM ANALYSIS

Analytical tools for gearbox noise and vibration can be extended by exploitation of cepstra to discover the periodicity in the frequency spectrum. The cepstrum can be considered as a spectrum of a logarithmic spectrum. The details are discussed in the Chapter 48. Comparison of both these functions is shown in Fig. 11. The spectrum frequency axis is replaced in the cepstrum by a querecence in time units. The cepstrum is sensitive to the components spaced in the frequency spectrum by a small difference. The cepstrum tooth-meshing components are situated at the very beginning of the querecence axis as its frequency belongs to the middle frequency range. The cepstrum is a useful tool in fault diagnostics of rolling bearings that are an obvious part of the transmission unit.

10 TRANSMISSION ERROR MEASUREMENTS

Noise and vibration problems in gearing are mainly concerned with the smoothness of the drive. The parameter employed to measure smoothness is the transmission error⁷ (TE). This parameter can be expressed as a linear displacement at a base circle radius defined by the difference of the output gear’s position from where it would be if the gear teeth were perfect and infinitely stiff. Many references have attested to the fact that a major goal in reducing gear noise is to reduce the transmission error of a gear set. Experiments⁸ show that decreasing TE by 10 dB results in decreasing the A-weighted sound pressure level by 7 dB.

Figure 10 Time response of the main-shaft gears and its FFT spectrum.

Figure 11 Spectrum and corresponding cepstrum.

The basic equation for TE of a simple gear set is given as

$$TE(m) = \left(\Theta_2 - \frac{n_1}{n_2} \Theta_1 \right) r_2 \quad (1)$$

where n_1, n_2 are teeth numbers of pinion and wheel, respectively, Θ_1, Θ_2 are angles of rotation of the mentioned gears, and r_2 is a wheel radius.

Transmission error results not only from manufacturing inaccuracies, such as profile errors, tooth pitch errors, and run-out, but also from a bad design. The pure tooth involute deflects under load due to the finite mesh stiffness caused by tooth deflection. A gear case and shaft system deflects due to load as well. While running under load, one of the very important parameters, tooth contact stiffness, is varying, which excites the parametric vibration and consequently noise.

There are many possible approaches to measuring TE, but, as Smith points out,⁹ in practice, measurements based on the use of encoders dominate. The sketch of the gear set consisting of the 21- and 44-tooth gears under test and attached incremental rotary encoders, designated by E1 and E2, is shown in Fig. 12. Both the encoders generate a string of pulses. As a consequence of Shannon's sampling theorem, a few pulses must be recorded during each mesh cycle. It means that the number of pulses produced per encoder revolution must be a multiple of the tooth number. If five harmonics of tooth-meshing frequency are required, then the number of pulses per gear revolution must be at least 10 times greater than the number of teeth. The encoder generating 500 pulses per revolution seems to be an optimum.

There are two approaches on how to process the pulse signals. The first one is based on the

Figure 12 TE measurement arrangement.

measurement of the time interval between adjacent pulses using the high-frequency pulse generator (e.g., up to 1 GHz in the Rotec signal analyzer) and the counter, which is triggered by the encoder output signals. The instantaneous angular velocity is primary information for TE evaluation and needs integration. Henriksson and Pärssinen present an example of this measurement.¹⁰ The second method is based on the phase demodulation of the sampled pulse signals, which is described below. This method gives as primary information the instantaneous rotation angle and is especially suitable for the FFT analyzers.¹¹

A perfectly uniform rotation of gear produces an encoder signal having in its frequency spectrum a single component at the frequency that is a multiple of the gear rotational frequency. The phase of this carrying component is a linear function of time. As the phase is the argument of the cosine function, it can be associated with the gear rotation angle. The nonuniform rotation results in small variation of the rotation angle around the mentioned linear function of time. In this case the basic frequency of the pulse signal is modulated, which gives rise to sidebands around the carrying component in the frequency spectrum.

The phase modulation signal is a part of the phase of an analytical signal that is evaluated using the Hilbert transform technique. The complex analytical signal is compounded from the real part, which is the sampled pulse signal, and the imaginary part, which is the mentioned Hilbert transform of the signal real part. As the angle of the complex values ranges from $-\pi$ to $+\pi$, the phase of the analytical signal (as the time function) contains jumps by reaching the value of $-\pi$ or $+\pi$ radians. The true phase can be obtained by the so-called unwrapping phase. The unwrapping algorithm is based on the fact that the absolute value of the difference between two consecutive samples of the phase is less than π . The described algorithm is called phase demodulation.

The Hilbert transform can be evaluated by using either FFT or a digital filter (Hilbert transformer). Before evaluating FFT, it is recommended to resample the measured signal according to the gear rotational

Figure 13 Frequency spectrum of phase-modulated signal generated by the E1 and E2 encoders.

frequency in such a way that the length of resampled time record equals to a power of 2, namely to at least 2048 samples per gear revolution for the 500-pulse encoder. The pulse signal order spectrum for the 2048-sample record ranges to the value of 800 orders. There is a space for ± 300 sideband components around the carrying component of 500 orders.

The gear speed variation at the tooth-meshing frequency results in the phase modulation of the impulse signal base frequency. As noted above the phase-modulated signal contains sideband components around the carrying component situated in Fig. 13 at $500 \pm 21k$ order for the 21-tooth pinion and at $500 \pm 44k$ order for the 44-tooth wheel, where $k = 1, 2, \dots$. Take notice of the fact that the dominating components in both the sideband families exceed the background noise level at least by 20 dB or even more. Both the spectra were evaluated from time signals that are a result of the synchronized averaging of 100 revolutions of gears under testing.

Phase demodulation of the averaged pulse signals results in the phase variation during a rotation of both the meshing gears. As in the case of the average tooth-mesh of the vibration signal, both the phase variation signal can be averaged again to obtain an averaged representative for angular vibration during the gear tooth pitch rotation. Angle variations can be easily transformed into arc length variations.

The arc length difference is not a final step for evaluation TE. As both the encoder signals are recorded separately, the true phase delay between these signals is to be detected. This problem can be solved thanks to the fact that the average tooth mesh responses, for example, in acceleration of some point on the gear case, to dynamic forces acting between meshing teeth are theoretically the same. Therefore, both the encoder pulse signals are sampled together with the acceleration signal. A two-stage averaging of the twice-measured acceleration signal gives average tooth-mesh responses that are delayed against each other. The lag for the maximum correlation gives the value of relative delay.

Transmission error is given as the difference between the angular vibration signals in the arc length produced by the meshing gears. The result for three times repeating tooth pitch rotations and two levels of loading is shown in Fig. 14.

11 EFFECT OF GEARBOX DESIGN PARAMETERS, GEAR QUALITY, AND OPERATION CONDITIONS

The averaged tooth-mesh signals are contact ratio sensitive. It is well known that contact ratio (simply, though not quite accurately stated, contact ratio is the average number of teeth in contact during a mesh cycle) is one of the most important parameters determining gear tooth excitation and thus noise level. Three examples of the average tooth-mesh signals, shown in Fig. 15, deal with helical gears under load differing in profile contact ratio (ϵ_α) while overlap ratio [face contact ratio (ϵ_β)] is approximately equal to 1.0. Total contact ratio (ϵ_γ) is indicated by the diagram legend. The value of the profile contact ratio,

Figure 14 Transmission error against rotation angle in tooth pitch rotation.

Figure 15 Effect of contact ratio on the average tooth-mesh acceleration signal.

which is less than 2.0, is called low contact ratio (LCR) gearing while the gearing with this parameter equal to 2.0 or more is designated as high contact ratio (HCR). The integer value for the profile contact ratio and the overlap ratio result in considerable reduction of gearbox vibration and noise. It can be estimated that introducing the HCR toothing results in reducing the noise level of gearboxes with LCR toothing by approximately 6 dB. Experiments⁸ show that the transmission A-weighted sound pressure level decreases at approximately 10 dB per 1.0 increase (4.0 through 5.0) in contact ratio.

Evaluation of the averaged tooth-mesh signal is an effective method for verifying contact ratio, detecting a regular error in tooth profile geometry and improving toothing by modification of tooth profile and load, while the envelope of acceleration signal during a complete revolution is important only for quality control.

The gear tooth quality is given by the permissible maximum values of individual variations. Individual variations are those variations from their nominal values, which are exhibited by the various parameters of the gear teeth, such as pitch, profile shape, base diameters, pressure angle, tooth traces, and helix angle. It is known that a gear could be absolutely perfect referring to these variations and yet be very noisy in the conditions of meshing. We can find in the tolerance data a few microns and have many times more deformations due to the loading. In reverse some low-noise gears are imperfect. An example of the effect of the gear tooth quality on the noise level emitted is shown in Fig. 16. However, it can be estimated that an improvement by class 1 of DIN 3961 quality results in a noise level reduction of approximately 1.5 dB. The data were taken from measurements on a truck gearbox with gears finished by grinding. Gear quality class is a weighted quantity that is influenced mainly by the variations in the tooth profile (tooth trace form or angle). The more significant difference in noise levels can be identified when comparing

Figure 16 Effect of mean gear quality on the A-weighted noise level in at 1 m.

the tested gears, which are finished by grinding or hobbing. The gearbox noise level correlates with the gear geometry deviations if the gearbox structure is stiff enough.

The research work on noise reduction employed different methods to identify the dynamic properties and to discover the dynamically “weak” parts of gearbox structures. Using ribs increases stiffness of the gearbox housing structure. In reality, the effect of these improvements, which are limited by the given gearbox structure, on the overall noise level is of small significance. However, they are important because after introducing these improvements the noise level of newly built units varies in correlation with errors of gear geometry. The most efficient improvement can be reached when the noise problem is controlled at its very source, which is the tooth contact of meshing gears.

An example of the effect of gearbox load on the rms value of gearbox acceleration is shown in Fig. 17. The gearbox design input torque is equal to 1200 Nm. To prevent the increase of vibration and consequently the noise level due to the teeth and gearbox structure deformation, the modification of the tooth profile and lead by crowning across the face and tapering of the lead is introduced.^{12,13} Comparison

Figure 17 Effect of load on rms acceleration.

of the modified toothing with the toothing, which is without modification, shows that the gear pair with the modified surface meshes more smoothly at nominal loading than the gears without modification. This design improvement can result in reducing the noise level by 3 dB.

12 TRANSMISSION FAULT DIAGNOSIS

Fault diagnosis is a topic discussed in Chapter 48. As stated above, the recorded signals depend on the operating condition given by rotational speed and load. To demonstrate the effect of load on the vibration signal, the response to the pitting on the tooth surface is shown in Fig. 18. The vibration signal of the loaded gears results only from time-varying tooth contact stiffness and overlaps the deviations in gear geometry or the local tooth defect.

It is well known that the vibration and noise level during the gearbox life test are maintained at a relatively stable level up to the moment when gear tooth fatigue crack¹⁴ starts as a very quickly developing process finishing with gear damage during a few minutes.

Continuous even wear of teeth results in increasing the higher harmonics of the tooth-meshing component.¹⁵ More details on the diagnosis of the gear faults are given in Taylor's handbook.¹

Acknowledgment The author is grateful to Prof. V. Moravec, the head of the team for developing the HCR gearing at the company TATRA at the beginning of 1990s, for his help and valuable comments dealing with gear design and accuracy.

CHAPTER 89

JET ENGINE NOISE GENERATION, PREDICTION, AND CONTROL

Dennis L. Huff and Edmane Envia
NASA Glenn Research Center
Cleveland, Ohio

1 INTRODUCTION

A jet engine is an air-breathing propulsion system that provides thrust for aircraft propulsion. Air is drawn into the engine through an inlet, is compressed through a fan and multiple compressor stages, heated through a combustor, expanded through multiple turbine stages, and exhausted from the engine nozzle. Collectively, these components produce the engine's propulsive force (i.e., thrust). Unfortunately, they also generate noise due to the conversion of a portion of the energy of the flow fluctuations into sound. The character of sound produced depends on the particular engine component. The fan, compressors, and turbines generate tones and broadband noise due to the unsteady flow impinging on both rotating and stationary blades. The combustor and jets produce broadband noise due to turbulent fluctuations in the flow field. In general, noise increases as the velocity of the flow through the engine increases. Reliable noise prediction methods are difficult to develop since they depend on accurate prediction of the unsteady flow field in and around the engine. Strategies for mitigating engine noise include modifying the unsteady flow field, redirecting the sound propagation, absorbing the sound using acoustical treatment, or combinations of all three.

2 BACKGROUND

Aircraft noise has been a problem near airports for many years. It is a quality-of-life issue that impacts millions of people around the world. Solving this problem has been the principal goal of noise reduction research that began when commercial jet travel became a reality. While progress has been made in reducing both airframe and engine noise, historically, most of the aircraft noise reduction efforts have concentrated on the engines. This was most evident during the 1950s and 1960s when turbojet engines were in wide use. This type of engine produces high-velocity hot exhaust jets during takeoff, generating a great deal of noise. While there are fewer commercial aircraft flying today with turbojet engines, supersonic aircraft, including high-performance military aircraft, use engines with similar exhaust flow characteristics. The Pratt & Whitney F100-PW-229, pictured in Fig. 1a, is an example of an engine that powers the F-15 and F-16 fighter jets. The turbofan engine was developed for subsonic transports, which in addition to better fuel efficiency also helped mitigate engine noise by reducing the jet exhaust velocity. These engines

were introduced in the late 1960s and power most of the commercial fleet today. Over the years, the bypass ratio (i.e., the ratio of the mass flow through the fan bypass duct to the mass flow through the engine core) has increased to values approaching 9 for modern turbofans such as the General Electric GE-90 engine (Fig. 1b). The benefits to noise reduction for high bypass ratio (HBPR) engines are derived from lowering the core jet velocity and temperature and lowering the tip speed and pressure ratio of the fan, both of which are the consequences of the increase in bypass ratio. The HBPR engines are typically very large in diameter and can produce over 100,000 lb of thrust for the largest engines. A third type of engine flying today is the turboshaft, which is mainly used to power turboprop aircraft and helicopters. An example of this type of engine is shown in Fig. 1c, which is a schematic of the Honeywell T55 engine that powers the CH-47 Chinook helicopter. Since the noise from the propellers or helicopter rotors is usually dominant for turboshaft engines, less attention has been paid to these engines insofar as community noise considerations are concerned. This chapter will concentrate mostly on turbofan engine noise and will highlight common methods for their noise prediction and reduction.

Over the years, aircraft noise reduction research has led to significant progress as indicated in Fig. 2, where noise levels from a few representative aircraft-engine combinations are shown using their noise levels in EPNdB (effective perceived noise level in decibels) as a function of the approximate year they entered service. While some of the noise reduction is due to design changes for engine and aircraft, most of the reduction comes from cycle changes to the engine such as the introduction of higher bypass ratio turbofan engines. Commercial aircraft use the EPNdB noise metric and distinguish takeoff and approach conditions. The three main certification points are takeoff (also called "sideline"), takeoff with cutback, and approach (see Chapter 125 for more information on aircraft noise metrics). The certified noise levels are regulated by organizations such as the Federal Aviation Administration (FAA) in the United States and are recommended by members of the International Civil Aviation Organization (ICAO) to provide international standards. Takeoff noise levels are usually dominated by the engine, while approach levels consist of sources from both the airframe and engine. In fact, some aircraft are dominated by airframe noise sources such

Figure 1 Various aircraft engine types.

Figure 2 Evolution of aircraft noise reduction.

as landing gear, flaps, and slats during approach. For more information on these noise sources, see Chapter 9. Military aircraft are not included in Fig. 2 since they are exempt from certification. However, there has been increased sensitivity by the general public to noise from these aircraft near air bases over the past few years. General aviation aircraft and rotorcraft are also not included in Fig. 2. In addition to EPNdB, other metrics such as A-weighted sound pressure levels for low-altitude flyovers are used.

Aircraft engine noise is primarily an aerodynamic source and is not produced by structural vibration. However, there are some cases, particularly for propeller-driven aircraft, where structural vibrations from the engines couple with the aircraft structural and acoustic modes in the cabin and cause high levels of interior noise. This distinction has given rise to the term *aeroacoustics* when describing aerodynamically generated noise. Engine noise is caused by the interaction of flow field's coherent and random fluctuations (i.e., turbulence) with the solid surfaces inside the engine producing tonal and broadband components of noise, respectively. Noise can also be produced by fluctuations in the flow field that radiate sound (such as jet noise). For more information on the fluid mechanics associated with aerodynamic noise, see Chapter 9.

3 ENGINE NOISE SOURCES

The major noise sources for a modern turbofan engine are shown in Fig. 3. The relative sound pressure levels from each component depend on the engine architecture and power setting. At takeoff condition, the fan and jet noise usually dominate. For approach condition, the fan usually dominates since the jet velocity is reduced. Noise from other components such as the compressor, combustor, and turbine is generally less than that from the fan and the jet. This is why most

of the noise reduction research over the past 25 years has emphasized fan and jet noise reduction. The noise radiated from the inlet includes contributions from both the fan and compressor but is primarily dominated by the fan. Aft-radiated noise is dominated by the fan and jet, but there can also be significant contributions from the combustor and turbine, which are highly dependent on the particular engine. The noise levels shown in Fig. 4 represent an average from engines that were available in 1992 that powered a medium-sized twin-engine aircraft such as the Boeing 757 or 767 (nominally 400,000 lb takeoff gross weight with 60,000 lb thrust from each engine). Engine component noise levels are also available for other aircraft types such as small business jets, small twin-engine aircraft such as the Boeing 737, and large four-engine aircraft such as the Boeing 747.¹

Typical radiation patterns (called source directivities) from various engine noise sources are shown in Fig. 5. Source directivity depends on the engine architecture, power setting, and noise source. Directivity can be used as a criterion to select only those engine noise sources that contribute to the community noise metrics. For example, tones from the turbomachinery can be analyzed using modal decomposition and expressed in terms of their cutoff ratio. The cutoff ratio is a measure of how well a mode can propagate inside the engine duct. Highly cut-on modes tend to radiate along the axis of the engine (both upstream and downstream) and do not impact the community since they are directed away from the ground and attenuate through the atmosphere. On the other hand, modes that are just cut-on propagate 90° from the engine axis, and acoustical treatment in the nacelle is most effective since the sound waves propagate directly into the liner. Modes that propagate from 30° to 60° from the forward engine axis are the most difficult to control. The

Figure 3 Dominant turbofan engine noise sources.

Figure 4 Typical engine effective perceived noise levels. It should be noted that the locations for the microphones are not the same for all three certification points.

use of modal analysis to characterize turbomachinery tones was pioneered by Tyler and Sofrin² and is still used today to understand engine noise sources.

4 NOISE REDUCTION STRATEGIES

Most of the engine noise reduction advances have come from changing the engine cycle and incorporating low-noise technologies. During the 1960s and 1970s, low-noise design guidelines were developed that include eliminating inlet guide vanes in front of the fan, incorporating acoustical liners in the fan duct and the core, increasing the spacing between rotors and stators, using lobed mixers on the exhaust, and developing “wide-chord” fans with lower tip speeds. Many of these advances have dual benefits for reducing noise and increasing the propulsive efficiency. Some of the techniques that have been developed over the past 25 years are highlighted for each engine component below.

4.1 Fan Noise

Fan noise research requires simulation of conditions representative of the engine operating during takeoff and approach. Static tests use an inflow control device³ (ICD), which resembles a large mesh golf ball that is usually much larger than the diameter of the fan and

is mounted on the inlet. It was discovered during the 1970s that running a fan without flow conditioning caused large-scale turbulence and ground vortices to be ingested into the fan producing extraneous fan noise in the process. The purpose of the ICD is to break up the turbulence into small eddies that decay rapidly to levels representative of atmospheric turbulence entering the engine in forward flight. Unfortunately, many good noise reduction ideas tested before this discovery were prematurely discarded because of contaminated data. An alternate approach is to run the fan in a wind tunnel with appropriately low levels of free-stream turbulence to simulate the forward flight conditions. If the wind tunnel is large enough, angle of attack simulations can also be done to make sure inflow distortions into the fan are not a major noise source.

Since it is difficult to extract the fan noise from engine spectra that contain other sources, most of the research on fan noise is done in fan rigs where the fan source can be isolated. Results from decades of tests have shown that fan tip speed and pressure ratio control the overall fan noise levels. For subsonic tip speeds, the interaction of fan wakes with the stators is the dominant source. This dependence has been demonstrated in recent *source diagnostic tests* at Boeing and the NASA Glenn Research Center.^{4,5} Methods

Figure 5 Typical noise radiation from turbofan engines.

for reducing this noise at the source include decreasing the fan tip speed, reducing the fan pressure ratio, increasing the fan/stator spacing,⁶ sweeping and leaning the stators to reduce tones,^{7,8} selecting favorable fan blade–stator vane ratios to reduce the tones,⁶ and reducing the number of stators to reduce the broadband noise.^{4,5} For supersonic fan tip speeds, the self-noise generated by the fan becomes an important contributor, especially for inlet-radiated noise. With the exception of multiple pure-tone (MPT) noise, less is known about the source mechanisms associated with the rotor self-noise since noise measurements are typically dominated by rotor–stator interaction source. Special experiments have been done to help isolate this source,^{4,5} but no noise reduction strategies have been successful beyond tip speed and pressure ratio changes, both of which affect fan aerodynamic loading.

Multiple pure tones, or “buzzsaw” noise, is associated with the rotor operating at supersonic tip speeds. This source is due to small blade-to-blade geometric differences (e.g., stagger angle) that cause the shocks on each blade to have a unique propagation characteristic upstream of the fan. Depending on the particular

fan, tones at multiples of the shaft order frequencies can be heard in the far field as the aircraft approaches an observer. Noise reduction methods for this source include rearranging the fan blades on the fan disk to modify the frequency content, using tighter manufacturing tolerances to minimize blade-to-blade differences, optimizing acoustical treatment in the inlet to absorb these tones, or using blade sweep to reduce the strength of the blade shocks and capture the associated normal shocks inside the fan blade passages.

Another fan noise source is the interaction of inflow distortions or inlet surface boundary layers with the fan. This source is believed to be secondary for well-designed nacelles where inflow distortions and boundary layers are minimized for performance and operability reasons. Depending on the diffusion downstream of the inlet throat and the tip clearance between the fan case and the fan tip, the boundary layer on the inlet may not interact with enough of the fan blade span to be a major noise source.

Acoustical treatment is used in turbofan engines primarily to reduce turbomachinery noise from the fan, compressor, or turbine. Since the liners need to

endure harsh environments (high temperature, cyclic weather conditions including ice and jet fuel by-products), materials are limited and often not optimal for maximum noise reduction. Liners usually consist of a face sheet with porosity to provide desired resistance without significantly increasing the skin friction. Sometimes a fine wire mesh is used in place of the porous face sheet. The face sheet covers cavities that are sized to provide the desired impedance over a range of frequencies for noise attenuation. Metal honeycomb is a common structure for the cavities. In some applications, multiple layers of liners are used that are designed to different peak attenuation frequencies to provide a wider bandwidth of suppression. Single, double, and sometimes triple degrees of freedom liners are used in modern engines. Cost and weight are also factors considered for liner selection. It is most common to use acoustical liners in the fan inlet and the bypass duct downstream of the fan on both the nacelle and the core cowl. The design of a liner starts with determining the "hard-wall" (no acoustical treatment) spectra and choosing a frequency range where attenuation is needed. It is best to use a perceived noise level (PNL) weighting (Chapter 125), which usually targets 2 to 4 kHz. Recent improvements in manufacturing methods have helped minimize the splices associated with the circumferential segments that make up the liner. The splices cause a spatial discontinuity of the acoustic impedance that could cause the fan noise to increase. Reducing the number of splices and circumferential extent of the splice increases the effectiveness of the liners. Higher bypass ratio engines have shorter inlets and nacelles to minimize aerodynamic drag, which compromise the available treatment area. So even though higher bypass ratio engines are quieter at the source, acoustical treatment can be less effective due to less treatment area.

To overcome the problem, several alternate methods have been developed recently such as scarf inlets and active noise control. Scarf inlets resemble a sugar scoop in that the lower lip extends further upstream than that at the top of the inlet. This redirects the inlet-radiated fan noise away from the ground. Acoustical treatment is used to absorb the acoustic rays that impact the sound pressure levels on the ground. While this idea was first developed in the 1970s, only recently modern computational fluid dynamic (CFD) methods have provided improved aerodynamic prediction methods to help make scarf inlets more practical. Boeing has developed a scarf inlet that integrates acoustical treatment to optimize the inlet for lower noise.⁹ Despite these advances, scarf inlets have not yet entered service.

Active noise control is still in its infancy for turbofan applications. While this technique has been successful in mitigating noise in simple configurations, such as plane waves in a ventilation duct, its application to reduce turbofan noise has proven to be very challenging. This is primarily because of the complexity of the noise source, which typically consists of many circumferential and radial modes for even a

single tone. Nonetheless, over the past 10 years, active noise control research has made significant strides (in idealized configurations), progressing from single frequency/mode cancellation to multiple frequency/mode cancellation involving both the inlet- and aft-radiated fan noise. A typical active noise control system consists of ring(s) of actuators to provide the cancellation source, a set of error microphones to monitor the cancellation level, and a control algorithm to provide real-time optimization of the noise cancellation. (A summary of active noise control systems is included in Chapter 63). The source actuators have been placed in various locations of the inlet and aft fan duct and sometimes imbedded in the acoustical treatment. One test,¹⁰ performed by BBN and NASA, used actuators embedded in the stators to provide more control over the radial spinning modes (Fig. 6). However, the number of error microphones and source actuators needed to reduce a complex fan noise source (especially at higher frequencies) is too large for practical applications. In addition, the actuators need to be robust, produce high-amplitude sound output, and be effective over a range of frequencies. Creative ways to reduce the system requirements and cost are needed to make active noise control feasible for aircraft engines. Another strategy for active noise control is to integrate it with the acoustic treatment to make the liners more effective. An example of this hybrid active/passive approach has been developed by Northrop Grumman.¹¹ A summary of active noise control research for fans can be found in an article by Envia.¹²

4.2 Jet Noise

Jet noise reduction research is also typically done in model-scale rig tests. This noise source is distributed along the jet plume and is responsible for the low-frequency rumble that can be heard as the aircraft is flying away from an observer. Since most of the jet noise is generated external to the engine, noise reduction methods are difficult to implement. It is important to simulate forward flight effects when evaluating jet noise reduction concepts since the strengths of the shear layers from the exhaust nozzles vary with forward flight speed.¹³ Generally, there is less jet noise in flight compared to the static condition. Reduction methods that work well for static tests often have a reduced benefit when forward flight simulations are included. Many engine noise tests are done on static test stands, which require corrections for jet noise using either model-scale data that includes forward flight or correlations based on previous experience. This raises the level of uncertainty and sometimes leads to incorrect jet noise assessments. Another major consideration is running the jets at realistic temperatures. Cold jets display different characteristics in the noise spectra than hot jets,¹⁴ and noise reduction concepts need to work for a range of operating conditions.

The major parameter controlling jet noise is the exhaust velocity gradient. The common rule of thumb holds that the jet noise varies with the velocity raised to the eighth power for jets with subsonic flows. This was first derived by Lighthill.¹⁵ For a single-flow, round jet

Figure 6 Active noise control for fan noise reduction.

with subsonic exhaust velocities, the jet noise spectra consist of broadband noise with a peak frequency that scales with the Strouhal number (fD/U , where f is the frequency, D is the jet diameter, and U is the fully expanded jet velocity). The most common and effective way to reduce jet noise is to simply reduce the exhaust velocity. For higher bypass ratio turbofans, the core stream velocity is reduced as more energy is extracted from the turbine. This reduces the relative velocity between the core and the bypass streams and between the fully mixed jet and the ambient air.

There are two basic types of exhausts on turbofans: internally mixed, where the core flow mixes with the bypass flow inside the nacelle, and separate flow nozzles, where the flows mix downstream of the nacelle exit plane. Lobed mixers are used for internally mixed engines to provide both noise reduction and performance benefits. They resemble cookie cutters located at the core nozzle exit (Fig. 7). The purpose is to mix the flow streams in a way that lowers the peak velocity exiting the engine without introducing additional turbulence that causes high-frequency noise. It also provides a favorable static pressure and temperature profile at the exit that can improve the engine thrust. Many experiments have been carried out that investigate different mixer designs by varying the penetration of the lobe into the bypass and core flows, the number of lobes, and the shape of the lobes. CFD methods are now able to aid the design of complex nonaxisymmetric mixers. While the performance assessments are fairly reliable, the link to noise generation and propagation is still a research topic. The optimum mixer design is dependent on the engine configuration and operating parameters. It is difficult to derive general noise reduction design guidelines other than being careful not to mix the flow

so aggressively that high-frequency noise generation penalty negates the low-frequency noise reduction benefit. In some applications, acoustical treatment is added to help absorb the high-frequency noise if it is generated inside the engine. Generally speaking, mixer designs with good aerodynamic performance (i.e., mixing with low losses) are also good acoustical designs.

Separate flow nozzles are common on larger engines. Until recently, there were no noise suppression methods implemented on engines for reducing the jet noise from these exhaust systems. In 1996, NASA worked with several U.S. companies to investigate the use of tabs and chevrons to mix the core and bypass flow streams for jet noise reduction. Chevrons, which resemble a sawtooth pattern on the trailing edge of the nozzle (Fig. 7), were found to reduce the jet effective perceived noise level by about 3 EPNdB without significant thrust loss. The success of all engine noise reduction methods is based on the amount of noise reduction that can be achieved without significant thrust loss. Similar to the internal mixers, the key is providing just enough mixing of the flow streams to impact the turbulence in the jet without increasing the high-frequency mixing noise. The penetration of the chevrons into the core and bypass flow is small but sufficient enough to generate streamwise vorticity into the shear layer, which reduces the velocity gradients in the plume. Over the past few years, chevrons have been introduced on new engines such as General Electric's CF34-10. Proceedings from a jet noise workshop sponsored by the AeroAcoustics Research Consortium (AARC) provide a good overview of recent progress in jet noise control and prediction.¹⁶

Figure 7 Lobed mixer (top) and chevron nozzle (bottom) are two practical methods for jet noise reduction.

4.3 Compressor Noise

There has not been much research done on compressor noise for many years. If it is a problem, it is usually identified as tones radiating from the inlet. These tones are easily identified using narrowband spectra in the far field, knowing the shaft rotational speed and the number of rotor blades in the compressor stages (blade passing frequency = number of blades \times shaft rpm/60). For compressors, rotor–stator interaction is the dominant noise source, especially due to the close rotor–stator coupling that may excite the potential field interaction between the adjacent blade rows in addition to the viscous wake interaction. The interactions are also more complex than those of the fan since multiple stages are involved. The blade passing frequencies and higher harmonics associated with each blade row create many tones in the spectra. Fortunately, transmission losses across the rotors and stators block the radiated noise from the stages deeper in the engine core. Attention is usually given to the first one or two

stages that do not get this benefit. The blade–vane ratio and tip speeds are carefully chosen to take advantage of cutoff using the theory of Tyler and Sofrin.² Another strategy is to select blade and vane numbers that produce counterrotating circumferential modes that are more efficiently blocked by upstream blade rows (the acoustic waves tend to hit the blades broadside and reflect rather than being transmitted through the blade row).

4.4 Combustor Noise

In modern turbofan engines, combustion noise is usually the lowest priority for noise reduction. Most of the research that was done in the 1970s is still used today to understand this source and provide design guidelines. Combustion noise propagates through the turbine stages and peaks at downstream angles centered around 120° from the inlet axis and has a broadband character that peaks anywhere from 400 to 600 Hz. It is sometimes hard to distinguish this source from the jet noise. Combustion noise is usually most apparent at low engine power settings such as idle. As the engine speed increases, the combustion noise becomes masked by the jet noise. Cross-correlation techniques using unsteady pressure measurements in the combustor, turbine exit, and far field have been used with limited success to identify this source. Examples of combustion noise reduction methods include increasing the number of fuel nozzles in the burners, decreasing the fuel–air ratio, decreasing the burner pressure, and decreasing the flow through the combustor.¹⁷

4.5 Turbine Noise

The character of turbine noise is similar to that of compressor noise in that it is mostly tones radiating from the multiple stages of the turbomachinery. The tones radiate aft through the shear layer between the core and bypass streams. This causes the tones to scatter into adjacent frequency bands and appear as haystacks when measured in the far field. Since there can be many tones, even with narrow-band analysis this source may appear as broadband noise. It is also difficult to distinguish aft-radiated fan noise from turbine noise. A common diagnostic technique is to use acoustical treatment in the tail-cone near the turbine exit and compare the spectra with the total spectra from the engine over a range of speeds. Turbine noise reduction concepts are challenging since the engine cores need to be compact to reduce engine weight, making less room available for conventional noise reduction approaches. Modern turbofans use fewer stages in both the compressor and turbine components with increased aerodynamic loading on the blades, which can increase the noise. Common noise reduction concepts include selecting the blade numbers and rotational speeds for cutoff or increased transmission loss¹⁸ and using acoustical treatment. Engines that can run the turbines at higher rotational speeds benefit from placing the tones at frequencies that are high enough to be less annoying.

5 ENGINE NOISE PREDICTION METHODS

To predict the noise from an engine, one must predict the noise from its constituent components, namely fan, jet, compressor, combustor, and turbine. Once the noise levels from individual components are predicted, they can be combined to develop a system-level noise prediction for the engine. The current state of the art in the engine system noise prediction capability is exemplified by the Aircraft Noise Prediction Program (ANOPP code)¹⁹ which actually includes provisions for both the engine and airframe. In its current form, the engine noise modules in ANOPP are empirically based owing to the complexity of the sources involved, but eventually it is hoped that those modules would be replaced by more sophisticated physics-based prediction capabilities. In the following sections an overview of the methodologies being used (or developed) for predicting noise from the various engine sources are discussed.

5.1 Fan Noise

Fan noise prediction methods can be grouped into three broad categories: empirical, analytical, and computational. In the first category methods, of which Heidmann's²⁰ is a good example, experimental data are used to construct correlations between appropriate fan noise metrics and operating parameters. Typically, the chosen noise metric is the EPNdB and the operating parameter is either the fan tip speed or its pressure ratio. The correlations are often constructed for overall fan noise levels, but improved results might be obtained by developing separate correlations for each of the contributing mechanisms of fan noise (see earlier discussion). While it takes experience and skill to discern the appropriate correlation relationships, once constructed these methods are easiest to use. The main shortcoming of the empirical methods is that their applicability is limited by the range of data used to construct the correlations. As a result, they cannot be reliably used to predict noise when the fan design and/or operating conditions lie outside of the envelope of the databases used to construct the correlations. These methods are widely used, principally as part of system-level prediction codes for engine design evaluation studies.

As the name suggests, the methods in the second category are analytical in nature, relying on first principles as well as phenomenological considerations of the noise generation and propagation processes. Most of the methods in this category are based on the acoustic analogy theory developed by Lighthill.¹⁵ In the acoustic analogy theory, the aerodynamic and acoustic aspects of the problem are treated separately. Mathematically, this is done by a rearrangement of the exact equations of the motion so that a linear wave equation is obtained whose left-hand side describes the propagation of sound and its right-hand side represents a "known" aerodynamic source that generates the sound. The aerodynamic source is to be measured, computed, or otherwise modeled independently. The solution to the wave equation is given formally in terms of integrals that describe convolution of the source distribution and propagation characteristics. Depending on the

level of approximations involved in the description of the fan geometry and/or flow conditions, the solution can be expressed either in closed form or may require the use of quadrature schemes to evaluate the solution integrals. The overall fidelity of these methods is predicated on the level of approximations used to describe the source(s), the fan geometry, and flow conditions. Many examples of analytical methods exist, among them that developed by Ventres et al.²¹ It should be noted that when very simple descriptions of fan geometry and flow conditions are used (i.e., flat-plate blades and uniform background flow), the aerodynamic and acoustic aspects of the problem can be combined into a single problem and solved simultaneously. Examples of such methods include one developed by Hanson.²² The analytical fan noise prediction methods can often be used to predict the trends, but they cannot be reliably used to predict the absolute levels correctly. A good example of a fan noise prediction code in this category is called V072,²³ which is used to predict tone levels produced as a result of the interaction between the fan wakes and fan exit guide vanes. Another class of methods in this category use Kirchhoff formula to compute the radiation of sound away from the source region once the appropriate information (usually acoustic pressure and velocity perturbations) are given in sufficient details over a surface enclosing the source region.

The third category of fan noise prediction methods encompasses those approaches that, like the analytical methods, start with the equations of motion but make little or no approximations regarding the fan geometry or flow field. The resulting coupled system of unsteady flow equations, therefore, retain their complexity and can only be solved numerically through the use of appropriate computational algorithms. These methods, generically called computational aeroacoustics (CAA) methods,²⁴ include linearized frequency-domain methods (e.g., LINFLUX²⁵) on the one end of the modeling spectrum and nonlinear time-domain methods (e.g., BASS Code²⁶) on the other. If, in addition to sound, the flow turbulence is also to be predicted, the computational complexity grows significantly. Depending on the range of turbulence scales to be computed directly, the calculation is referred to as unsteady Reynolds averaged Navier–Stokes (URANS), large eddy simulation (LES), or direct numerical simulation (DNS). The latter approach can be used to compute the unsteady flow down to the smallest turbulence eddy sizes where viscosity converts the kinetic energy to heat. While the application of LES and DNS methods for predicting noise from realistic fan configurations is still years away, with recent advances in computer hardware and computational algorithms, the CAA methods that compute only the sound field (like LINFLUX) are beginning to take their place in the "tool box" of fan noise prediction methods. Figure 8 shows a comparison of the predicted and measured modal acoustic power levels for two different stators. The V072 code predicts the change in the total power from one stator to the

Figure 8 Example of fan tone noise prediction capability. Results shown are for rotor-stator interaction noise at a simulated approach condition.

other accurately but fails to predict the modal distribution correctly. The LINFLUX code, on the other hand, predicts both the trends and absolute levels rather well.

5.2 Jet Noise

Jet noise prediction methods can also be grouped into the same three categories as those for fan noise. The empirical methods, such as the SAE,²⁷ StoneJet,²⁸ and Fisher and Morfey,²⁹ rely on correlations between the noise level (typically third-octave sound power level) and such jet parameters as the nozzle diameter, exhaust velocity, and exhaust temperature. Correlations are typically developed for round single-stream cold jets, so more complicated jet configurations (e.g., hot, multiple-stream, nonaxisymmetric, nonconcentric, etc.) are represented by a round jet with equivalent velocity, temperature, and diameter. Methods like the SAE²⁷ make no distinction between the various noise-producing regions of the jet, while others (like StoneJet²⁸) divide the flow field into regions with different source characteristics. Due to the differences in the principal mechanisms involved, there are separate correlations for subsonic and supersonic jets. As in the case of fans, the empirical jet noise prediction methods are widely used as design evaluation tools.

Most widely used analytically based jet noise prediction methods are based on a variant of the

acoustic analogy theory due to Lilley,^{30,31} which accounts for sound refraction and other effects due to nonuniformities in the background flow (assumed to be parallel and transversely sheared) as part of the wave operator. A notable exception is the JET3D code,³² which uses Lighthill's original theory. As in the case of the fan, the aerodynamic source of jet noise must be calculated separately. This is usually done through the use of CFD, which provides both the background flow through which sound propagates, the source strength distribution in the form of intensities, and integral time and length and scales of turbulence. The most widely known example of these methods is the MGB code, which is named after its original developers Mani, Gliebe, and Balsa.³³ Over the years, it has been shown that the approximations employed in the MGB code are too restrictive, and, as a result, a number of improved jet noise codes have been developed. These include the JeNo code,³⁴ the Tam model,³⁵ and the Morris model.³⁶ The distinction among these codes lies in subtle, but important, differences in the modeling and interpretation of the aerodynamic sound source. When high-fidelity CFD is used to model the source, often reasonably accurate predictions are obtained using these methods. As an example, measured and predicted spectra for a single-flow subsonic round jet at two far-field angles (relative to the engine inlet

Figure 9 Example of jet noise level prediction capability. Results shown are for a single-flow, subsonic jet (Mach number $M = 0.9$.)

axis) are shown in Fig. 9. The predictions include those from the JeNo code as well as a variant of the MGB code called MGBK.³⁷ The level of agreement between jet noise predictions and experimental data varies for more complex nozzle designs and is a current research topic. These methods generally apply when the jet exit velocity is subsonic relative to the ambient speed of sound. The methods for calculating noise from supersonic jets³⁸ have not yet been developed to the same level of fidelity and utility as the ones for subsonic jets.

Over the past decade, significant progress has been made in applying CAA to jet noise prediction and, as in the case of fans, less is modeled a priori and more is computed directly. A host of methods³⁹ including URANS, LES, and DNS have been used to compute the jet noise directly from the first principles. Of course, it will be some time before the CAA methods can routinely be used for design work. To put the scale of the challenge in perspective, the landmark

DNS simulation by Freund⁴⁰ required a massively parallel computer running several months to compute the unsteady field for a jet at the Reynolds number of $Re = 3500$. By contrast, a realistic jet from a turbofan engine at takeoff has a Reynolds number closer to 10^7 . Since the computational complexity (as measured by the number of grid points) is thought to be proportional to $Re^{9/2}$, much more powerful (and cost effective) computers are needed for CAA to become a practical design tool. For now, CAA is principally a diagnostic tool to investigate the myriad of subtle physical processes that contribute to jet noise.

5.3 Core Noise (Compressor, Combustor, and Turbine)

Unlike the fan and jet components, the prediction tools for core noise are mostly empirical and are based on work that was done in the 1970s. This is mainly a reflection of the fact that for modern turbofans the

dominant sources are the fan and jet, and so they have historically received most of the development work. The most widely used tools today for predicting core noise are a collection of correlations for predicting compressor, combustor, and turbine noise.^{17,20,41–43} The correlations are used to fit experimental spectra in regions where the particular component is thought to dominate. Since the overall core levels are below the fan and jet noise, only portions of the spectra can be matched, which makes this procedure difficult especially as the noise levels from other sources are similar and there are no distinguishing characteristics in the spectra. Source diagnostic tests are used to help isolate the sources and are the basis for many of the correlations available today. With the progress that has been made in developing noise reduction technologies for the fan and jet components, the core noise is beginning to receive more attention as the next obstacle to be tackled for designing quiet aircraft engines. It is likely that within the next decade, analytical as well as computational tools will be developed to help improve the core noise prediction capability.

6 FURTHER READING

For more information on aircraft and engine noise, there are a few excellent references available. One is the book by Smith⁴⁴ published by the Cambridge University Press that provides a comprehensive overview of aircraft noise. Another is a technical report originally published by NASA in 1991 that has since been published by Springer.⁴⁵ In this report, each noise source is explained in detail, and a comprehensive list of references is also provided at the end of each chapter.

CHAPTER 90

AIRCRAFT PROPELLER NOISE – SOURCES, PREDICTION, AND CONTROL

F. Bruce Metzger
Metzger Technology Services
Simsbury, Connecticut

F. Farassat
NASA Langley Research Center
Hampton, Virginia

1 INTRODUCTION

A thorough understanding of propeller noise requires knowledge of sources, propeller noise measurements, propeller noise prediction methodology, and methods of control. Since the study and control of propeller noise has been the subject of research since the early 1900s, there is an extensive body of literature on the subject that allows the reader to thoroughly investigate all aspects of propeller noise, its prediction, measurement, and reduction.

Prediction of propeller noise is fairly complicated but is tractable analytically if computerized methods are used. Even personal computers can be used to produce accurate and almost instant predictions for most general aviation and commuter aircraft propellers. It should be noted, however, that accurate predictions of noise require methodology that addresses the influence of the flow field in which the propeller operates. Predictions may be made both in the time domain and the frequency domain. Noise reduction methods can be based both on experimental tests and theoretical predictions. The contribution of piston engine noise (particularly at lower propeller rotational speeds) makes a substantial addition to aircraft flyover noise.

2 DESCRIPTION OF PROPELLERS, THEIR INSTALLATION, AND THE CHARACTER OF NOISE PRODUCED

Propellers are open rotors. In smaller general aviation and ultralite aircraft they operate with fixed pitch. In larger general aviation and commuter aircraft they operate with adjustable blade pitch to improve aircraft performance. Smaller aircraft have two-blade propellers, while larger aircraft have three to as many as eight blades. Also, advanced propellers have used the counterrotation concept with two blade rows on the same axis of rotation. The front and rear blade rows, with sometimes different blade numbers, operate in opposite direction of rotation.

Most propellers are mounted on the nose of the aircraft or on the nose of nacelles on the aircraft wings. There are only a few pusher installations due to blade structural problems and noise associated with

interaction with disturbances created by the fuselage, wing, or tail surfaces.

Propeller noise can be described as mostly tone like. Tones produced by an aircraft during a flyover are primarily associated with the production of propeller thrust and torque forces (called loading noise) and the volume of the blades (called thickness noise). At high subsonic or supersonic operating conditions, the blades also produce tone noise due to nonlinear effects. However, this mechanism is not significant for the conventional propellers used in general aviation and commuter applications. Counterrotation propellers produce tone noise due to the interaction of the two blade rows. Under static conditions the ingestion of atmospheric turbulence and ground vortices or vortices originating on the aircraft also causes tonelike noise. This disappears as the aircraft accelerates for takeoff. There is also a broadband noise component of propeller noise due to interaction of the blades with turbulence from atmosphere or from the wake of any upstream aircraft structure with the blade leading or trailing edges.

3 PROPELLER NOISE SOURCES

The spectrum of the propeller noise has both discrete and continuous components. The discrete components are called tones. The continuous component of the spectrum is called the broadband noise. In this chapter the classification of propeller noise sources will be based on the mathematical model of the acoustical analogy,¹ which is used universally in the propeller industry. There are three kinds of propeller noise sources. These are the thickness, the loading, and the nonlinear or quadrupole sources. These sources generate the thickness, loading, and quadrupole noise. The thickness and loading sources are blade surface sources while the quadrupole sources are volume sources in the vicinity of the blades. All these three sources can be steady or unsteady from the point of view of an observer sitting on the blade surface. The unsteadiness can be further classified as periodic and aperiodic or random. As a general rule, steady and periodic sources produce tone noise while random sources produce broadband noise. It is important to remember that the most important source of broadband noise for propellers is the random loading source. Furthermore,

for general aviation and commuter aircraft propellers, the thickness and loading sources are the most important sources of noise generation.

The thickness noise is generated by the blade volume, which causes the displacement of the air (i.e., pushing the air out near the leading edge and sucking the air in near the trailing edge) as a propeller blade rotates. The thickness noise source is also said to be of monopole type. The monopole strength per unit area is the density of the undisturbed air times the local normal velocity of the blade surface. The thickness noise source is a strong function of the propeller helical tip speed, but it also depends on the spanwise distribution of blade airfoil shape, blade chord, and blade thickness (particularly near the blade tip). This source is, in general, steady or periodic (e.g., when the aircraft forward velocity vector is not parallel with the propeller axis). There is no experimental evidence of broadband noise generation by random thickness sources (which exist when the blade surfaces have random vibration), although this is a theoretical possibility. Therefore, for all practical purposes, the thickness sources of a propeller generate only tones. The directivity of the thickness noise peaks in or near the plane of the propeller disk.

Loading noise sources depend on blade surface pressure. Loading noise source is said to be of the dipole type. The dipole strength per unit surface area is the local blade surface pressure, and the dipole axis is along the local normal to the surface. Blade surface pressure generates the propeller thrust and torque. For the first few harmonics of a low-speed propeller, the Gutin formula² gives the noise level in terms of the net thrust and torque. In general, it can be shown mathematically that the loading noise of a propeller at moderate or high tip speeds cannot be related to its net thrust and the torque. Nevertheless, the Gutin model is a useful mental picture. From this simple point of view, the loading noise is said to be generated by the thrust and torque.

The steady and periodic loading sources produce tones. Steady loading sources from the blade steady surface pressure produce the useful thrust and torque. The periodic loading sources are generated by periodic surface pressure fluctuations. These are caused by any phenomenon that is periodic, for example, by the nonuniform inflow into a propeller at an angle of attack during the climb and descent. Counterrotation propellers experience unsteady loading due to the aerodynamic interaction of the front and rear blade rows. Random pressure fluctuations on the propeller blades are produced by the ingestion of atmospheric turbulence or vortices that originate on the ground or on the fuselage. One must be careful in interpretation of the noise generation process when turbulence is ingested into the propeller disk. Hanson³ has shown that when turbulent eddies are sucked into a static propeller, they are stretched to such an extent that the blades intersect each eddy for many revolutions at the same region of blade surface. Such a phenomenon produces periodic surface pressure fluctuations that generate tonelike noise. For a propeller in forward flight, the atmospheric turbulent eddies do not have enough time to stretch

considerably and, thus, blade-turbulence interaction is a very inefficient phenomenon in producing tonelike noise.

In general, spatially random pressure fluctuations on the blade surface produce broadband noise. Turbulent eddies, which pass completely through the propeller disk in a time scale much shorter than the period of the revolution, and intersect the blades at random locations, produce broadband noise. The directivity of the loading noise peaks out of the propeller disk. Note that the thickness and the loading noise of a propeller at an observer position are not, in general, in phase. This means that there is a possibility of partial or even full cancellation of thickness and loading noise at some points in space. Hanson⁴ showed that at some points in space, sweeping the blades also has a favorable effect in reduction of the peak values of both the thickness and loading noise. This idea can be used in the reduction of the level of radiation in the direction of peak directivity.

For piston engine-driven aircraft Dobrzynski has reported⁵ that additional propeller tone noise is generated by nonuniform torque transmitted to the propeller due to impulses generated by the engine firing. Such impulses generate both unsteady thickness and unsteady loading noise.

Quadrupole sources are important when the flow over the propeller airfoil is transonic or supersonic. The quadrupole or nonlinear noise then should be added to the thickness and loading noise. Note again that thickness, loading, and nonlinear noise are not, in general, in phase. The quadrupole source strength per unit volume is basically the Reynolds stress. For propeller noise prediction, one should only be concerned with the steady sources. Fortunately, Hanson and Fink⁶ have shown that the quadrupole sources are not significant noise generators for conventional propellers but could be important in generation of the noise of highly loaded high-speed propellers such as propfans.

For a single propeller, the tones are harmonics of the blade passage frequency (BPF). This is so even for the tones generated by blade-turbulence interaction. The BPF is the product of the shaft frequency and the blade number. For counterrotation propellers, the number of blades on the front propeller may be different from that on the rear propeller so there will be two different BPFs. As in the case of single propellers, the tones will be the harmonics of the BPFs as well as additional tones called interaction tones.⁷

4 PROPELLER NOISE MEASUREMENTS

Propeller noise measurements are made (1) under static conditions, (2) with ground-mounted microphones as an aircraft flies overhead, (3) on the surface of an aircraft, and (4) in wind tunnels to simulate flight under controlled conditions. Propeller noise measurements are also made within the cabin of an aircraft to address passenger comfort, but this is beyond the scope of this chapter as it is influenced by interaction of the propeller noise with structural response of the fuselage and with cabin volume resonances.

In the past, many experimental research programs were conducted where the noise of a propeller was

measured while the propeller, or the aircraft on which the propeller was mounted, was stationary. At that time it was not recognized that the noise sources dominating the static propeller were different than those that dominated a propeller in flight. Under static conditions the ingestion of atmospheric turbulence or ground or fuselage vortices caused tonelike narrow-band random noise to be a dominant mechanism so the levels measured could not be related to that which occurred during an aircraft flyover. The reader is cautioned to use static measurements only as an indication of noise under static conditions.

Ground-level measurements of propellers during aircraft flyovers are important not only for research programs but also for noise certification and evaluation of the impact of propeller aircraft noise on the environment. For research programs, microphones should be mounted flush with the ground surface since microphones mounted above the ground produce results that are influenced by the constructive and destructive interference of the sound propagating directly from the aircraft to the microphone and the sound propagating from the aircraft that is reflected from the ground to the microphone. Note that, when comparing flyover measurements with noise predictions, propagation effects must be considered. Also, recent research has shown that the engine on propeller-driven airplanes is a significant noise source. Intermittent combustion engines commonly found on general aviation aircraft are known to produce tones that may occur at the same frequencies as propeller noise, so this must be considered in any research program. Also, shielding and scattering effects from the aircraft fuselage and wings may influence the noise reaching the ground.⁸ Measurements of propeller noise are also made on the surface of multiengine aircraft to provide information for design of fuselage treatment to reduce cabin noise. These measurements are made with microphones mounted flush with the fuselage surface.

Measurements of propeller noise are made at full and model scale in wind tunnels. In some cases acoustically treated tunnels are used where the microphones are placed in the tunnel flow. Therefore, microphone configurations that minimize self-noise caused by interaction with the tunnel flow are needed to allow the accurate sensing of the propeller noise. In other cases an open jet tunnel is used for measurements. Here, an anechoic chamber surrounds the open jet and microphones are placed outside the jet in still air. This eliminates the problem of interaction between the microphone and the tunnel flow but introduces the requirement to correct the data for the passage of the propeller noise through the shear layer surrounding the open jet. The advantage of tunnel testing is that operating conditions can be precisely controlled, and there are no flight safety concerns that exist in aircraft flyover tests.

5 PROPELLER NOISE PROPAGATION EFFECTS

In this chapter the effects of propagation from the propeller source to the point where it is heard or measured are briefly discussed. A more extensive

discussion of these effects can be found in Ref. 9 and elsewhere in this book.

5.1 Doppler Frequency Shift

This is the upward shift in frequency observed as a sound source approaches a stationary listener to a lowering of frequency after the sound source passes by. For propeller aircraft flyover noise where the source is dominated by tones, this effect must be addressed in any accurate prediction procedure. For propeller noise heard or measured where both the propeller and listener or measurement equipment is traveling at the same speed, there is no Doppler frequency shift. In acoustical wind tunnels where the propeller and measuring equipment are stationary, there is no Doppler frequency shift even though the propeller is experiencing the wind tunnel airflow. It should also be noted that additional Doppler frequency shift can also occur during aircraft flyover tests if significant wind conditions exist. This, of course, would not occur during aircraft noise certification flights where low wind speed is a requirement.

5.2 Atmospheric Refraction Effects

As sound from an aircraft in flight propagates to the ground, refraction occurs due to the change in temperature and pressure that occurs naturally in the atmosphere. Refraction also occurs as propeller noise propagates through the fuselage boundary layer to a measurement location on an aircraft.

5.3 Scattering and Shielding by Wing and Fuselage

With a wing-mounted propeller the noise reaching the fuselage can be affected by the presence of the fuselage or wing. At higher frequencies the fuselage acts like an infinite plate when receiving normal incidence sound and produces perfect pressure doubling (an increase of 6 dB compared with the level that would occur if the fuselage were not there). At nonnormal incidence the sound is scattered and measured levels are less. As the measuring point on the fuselage is moved toward the opposite side of the aircraft from the propeller, shielding further reduces noise. This is an area in need of further research. Some recent works on this problem are reported by Dunn and Tinetti.⁸

5.4 Atmospheric Absorption

As sound propagates through the atmosphere, there is a reduction in level due to absorption. This is in excess of the reduction in level that occurs due to normal spherical spreading (6 dB per doubling of distance from the source). In general, noise at high frequencies is absorbed more as it propagates. Procedures to calculate this effect as a function of temperature and relative humidity of the atmosphere are available, but the effects are small unless the aircraft noise propagates to the ground from a high altitude.

5.5 Ground Reflection Effects

For noise certification of propeller-driven airplanes the measuring microphone is sometimes mounted

above the ground. Therefore, the sound from the airplane propagates directly to the microphone and also propagates to the ground and is reflected to the microphone. The direct and reflected sound travels in two path lengths so it is combined at the microphone with constructive and destructive interference. If the noise of the flyover is to be predicted accurately, the effect must be included in the prediction procedure.

5.6 Excess Ground Attenuation

When the sound of a propeller propagates laterally while the aircraft is on or near the ground, it has been found that the noise level is less than that found when the aircraft flies overhead even though all effects of propagation have been considered. Wing and fuselage shielding may explain some of this effect, but other effects may occur that are not understood analytically. One possibility is that noise propagating near the ground from the aircraft to the measuring station is being absorbed by the ground cover.

6 PREDICTION METHODS AND COMPARISON WITH MEASUREMENTS

Since 1919 attempts have been made to predict the noise of propellers. Morfey,¹⁰ Farassat and Succi,¹¹ and Metzger¹² provide references for this work. Early work was hampered by a lack of computers for processing the complex calculations of theoretical formulations. Also, these early efforts were hampered by limitations in experimental equipment for measuring noise. Some progress was made in the time period up to the early 1950s, and the advent of computers at that time led to the development of methods that addressed a significant portion of the propeller noise generation process. Between the 1950s and early 1970s some progress was made in refining the prediction methods. Empirical methods were also developed in this time period that provided an indication of the effects on noise of some operating and geometric parameters without having to use computer calculations.

Since the early 1970s there has been a renewed interest in propeller noise prediction. This has been driven by the need to design propellers for general aviation and commuter aircraft to meet international noise certification limits, to evaluate environmental impact of aircraft noise around airports and in national parks, and as the basis for controlling propeller aircraft cabin noise. Both empirical and theoretical methods were developed in this time period. The empirical methods were generally refinements of earlier methods, but some also used regression analysis of propeller aircraft databases to define improvements. In the 1980s the need to control the noise of the propfan high-power advanced high cruise speed turboprop inspired the development of new methodology. Most of the recent theoretical methods have been based on the acoustical analogy proposed by Lighthill in 1952.¹³ Also, computational aeroacoustic methods based on the Euler equation have been developed.¹⁴ Prediction methodology in the time domain is discussed in this chapter's Farassat references. Prediction methodology

in the frequency domain is discussed in this chapter's Hanson references. Prediction methodologies by both authors have reached a stage in development where predictions compare quite well with measurements.

Prediction of propeller noise is fairly complex but is tractable analytically if computerized methods are used. Even personal computers can be used to produce almost instant predictions for most propellers. It should be noted, however, that accurate predictions of noise require detailed analysis of the influence of the effect of the flow field in which the propeller operates. Also, it has been established that engine noise is a contributor to aircraft flyover noise (particularly at lower propeller rotational speeds). Some methodology is available to address this noise source, but it is less well developed than propeller noise methodology.

6.1 Empirical Methods

Prediction of propeller noise has occupied researchers for decades. Complex theoretically based methods do exist that have been extensively refined for use in optimizing propeller designs. There is, however, a need for a simple empirically based method for preliminary design studies.

In May 1977 an empirically based graphical procedure for predicting sound pressure levels produced on the ground by propeller-driven airplanes in flight was published in the Society of Automotive Engineers (SAE) Aerospace Information Report 1407.¹⁵ Over the years, as additional sets of sound pressure level data for propeller-driven airplanes became available, the procedure was refined. The refined procedure was developed over a period of several years by the SAE Aircraft Noise Committee with the intent to publish it as an Aerospace Recommended Practice (ARP).¹⁶

Comparisons of flyover measurements and the ARP empirical predictions, in some cases, show good agreement. For example, comparison with the data of Dobrzynski and Gehlhar¹⁷ showed remarkably good agreement. These flyover tests used propellers with two to six blades with the diameter reduced by 5% for each increase in blade number. Figure 1 shows the comparison of the the Dobrzynski measurements and the ARP predictions. ARP empirical predictions in the figure are surprisingly good for the two-, three-, and four- blade propellers, but predictions for the five- and six- blade propellers show noticeable disagreement with the measurements. This is probably due to the presence of engine noise in the flyover noise data, which is not addressed in the ARP prediction procedure. Other studies using more refined methods that include the ability to predict engine noise support this opinion.

Since the ARP method does not address the effect on noise of blade planform, airfoil thickness, and airfoil shape, the agreement between prediction and measurement shown in Fig. 1 may not be the norm. The agreement shown in the figure does indicate that the ARP is satisfactory for preliminary design studies. However, the reader is cautioned that propeller thrust is not a parameter used in the ARP so the influence, on thrust, of changing horsepower cannot be assessed.

Figure 1 Measured and ARP-predicted effect of blade number on flyover noise level.

6.2 Theoretical Time-Domain Methods

Time-domain (TD) methods are of more recent origin than the frequency-domain (FD) methods. There are two reasons for the surge in interest in TD methods since the early seventies. First, the development of high-speed digital computers has made it possible to seek a numerical solution to the propeller acoustics in TD. Second, advances in generalized function theory have helped both in formulating the governing wave equation of acoustics of rotating blades and solving this equation. The most significant development in this area was the publication of a study by Ffowcs Williams and Hawkins¹ in 1969 based on Lighthill's acoustical analogy. These authors derived the Ffowcs Williams and Hawkins (FW-H) equation, which is a generalization of Lighthill's jet noise equation.¹³ The FW-H equation is a linear wave equation in terms of the density perturbations in the air with three inhomogeneous source terms known as the thickness, loading, and quadrupole sources. We have already discussed the classification of propeller noise sources in Section 3.

There are many equivalent solutions of the FW-H equation in TD.¹⁸ In general, time-domain methods require the detailed propeller geometry, kinematics, and the steady and unsteady blade surface pressures from aerodynamic codes. For a propeller in forward flight, the most important cause of the unsteady blade surface pressure is the nonuniform inflow into the propeller caused either by the flow field of the intake system or the nonaxial flow into the propeller disk. The calculation of the unsteady blade loads is difficult and time consuming on a computer. However, such calculations are becoming available and should result in more accurate prediction of propeller noise in TD.

A more recent advance in TD noise prediction is the realization that to include the most important nonlinear effects one should use the FW-H equation applied to a penetrable data surface that encloses the propeller blades.¹⁹ In the conventional application of the FW-H equation, the blade surface itself that does not allow fluid penetration is the data surface. This use of the FW-H equation with penetrable (or permeable) data surface appears to be the ideal method for the prediction of high-speed propeller noise.

Time-domain methods complement frequency-domain methods in understanding propeller noise generation. Technically, both methods require the same amount of information for noise prediction. In specific cases, one may be able to accept approximations to blade geometry and loading. In general, it is prudent to use as little approximations of the input data as possible to ensure the quality of the predicted data. In the development of propeller noise prediction codes, one should pay much attention to devising efficient algorithms for number crunching. It is, therefore, highly recommended that one use existing propeller noise prediction codes or do a thorough study of the propeller noise literature before embarking on code development.

6.2.1 Farassat Two formulations of Farassat are used in the propeller noise prediction code ASSPIN (Advanced Subsonic and Supersonic Propeller Induced Noise).²⁰ This code includes only the thickness and loading source terms of the FW-H equation. The propeller blades are divided into panels each of which radiates independently to the observer. The observer can be stationary with respect to the ground or be moving with the aircraft. The selection of the formulations is based on the following criteria. For

panels traveling at subsonic speed, formulation 1A²¹ is used exclusively for noise prediction. For panels traveling at transonic or supersonic speeds, the Mach number in radiation direction M_r is calculated first at emission time or times. If the Doppler factor $|1 - M_r| > 0.05$ at all the emission times, formulation 1A is used to predict the noise generated by the panel. Otherwise, formulation 3²² is used. Thus, for panels traveling at transonic or supersonic speeds, ASSPIN uses both formulations 1A and 3 depending on the size of the Doppler factor at the emission times of the panel. ASSPIN has also been used for counterrotation propeller noise prediction.

References 22 and 23 present results of TD noise prediction for two supersonic propellers (propfan) and comparison with measured data. The comparisons are generally good to excellent, particularly in the region of maximum noise radiation. Further comparisons of TD predicted and measured high-speed propeller noise for nonaxial inflow are presented in Ref. 24. In an accompanying study in the same journal, Hanson has presented similar calculations in FD with favorable agreement with TD results under almost identical geometric, kinematic, and aerodynamic input data as used in the TD predictions.

Farassat now advocates the use the FW-H equation with penetrable data surface for high-speed propellers and propfans. Since the flight speed of the aircraft is subsonic, only formulation 1A is used on the penetrable data surface in this case. An unsteady aerodynamic code supplies the input data. The computation time and complexity is considerably reduced compared to the use of ASSPIN.

Formulation 1A is used in the National Aeronautics and Space Administration (NASA) comprehensive aircraft noise prediction code, and the helicopter rotor noise prediction code WOPWOP. All NASA codes use this highly efficient formulation using exact blade geometry and kinematics. These codes are run on a desktop computer.

6.2.2 Dobrzynski Dobrzynski²⁵ developed a method that allows the prediction of A-weighted noise level as a function of time for flyovers of general aviation aircraft. The contribution of both engine and propeller noise as measured by a microphone at ground level is predicted. The starting point for development of this method was predictions of the noise of 11 general aviation aircraft using a time-domain method based on Farassat's solution of the FW-H equation. These results were calibrated relative to actual flyover measurements of the 11 aircraft.

The method predicts noise as a function of propeller blade number, propeller diameter, propeller revolutions/minute (rpm), propeller power absorbed, and flight altitude. The most significant parameter is the propeller tip helical Mach number. This is the square root of the sum of the propeller rotational tip speed squared and the flight speed squared with the resulting value divided by the speed of sound.

A unique feature of Dobrzynski's method is the ability to include engine noise. This is a function

Figure 2 Propeller and engine noise contributions to flyover A-weighted noise level.

of operating engine power and rpm as compared with maximum engine power and rpm. The separation of propeller and engine contributions deduced from flyover noise measurements and modeled in Ref. 25 is shown in Fig. 2. Engine noise generally dominates the flyover noise of a piston engine powered general aviation aircraft at times before and after the flyover of the aircraft. The propeller noise shows a sharper peak in amplitude near the time when the aircraft is directly overhead. This propeller noise peak dominates the peak flyover noise of most general aviation aircraft. As aircraft flyover noise is reduced by optimizing propeller design, the total aircraft noise is more influenced by engine noise. It is possible that an engine muffler may be required at some point to achieve significant reductions in general aviation aircraft noise.

Dobrzynski's report shows remarkably good agreement between predictions and measured flyover time history as well as maximum A-weighted flyover noise levels for most of the general aviation aircraft considered. The most significant discrepancy was found for an aircraft with very short engine exhaust pipes leading from each cylinder and exiting the aircraft just below the wing/fuselage. The lack of any muffling of the exhaust and the presence of reflecting surfaces at the point where the exhaust flow exits the aircraft is believed to cause a significant noise level compared to more typical aircraft.

6.3 Theoretical Frequency-Domain Methods

Hanson^{4,6,7,26–35} has been one of the prime developers of the frequency-domain methodology for propeller noise prediction. The reader interested in a single summary of this approach should review Ref. 9. His extensive work since the 1980s has been the basis for design of both single rotation and counterrotation propfans and general aviation/commuter propellers.

His work has been the basis for several propeller noise prediction methods. The first is the Unified Aeroacoustic Analysis for High-Speed Turboprop Aerodynamics and Noise.³⁶ His work was also the basis of two other methods, the Propeller Acoustical Change Estimation (PACE) Model³⁷ and the General Aviation Integrated Noise (GAIN)³⁸ Method, for predicting the noise of conventional single-rotation propellers used on general aviation and commuter aircraft. These methods are discussed below.

6.3.1 Propeller Acoustical Change Estimation

Model PACE³⁶ is a theoretical frequency-domain method. Its purpose is to provide a user-friendly tool for estimating propeller noise based on propeller geometry, operational information, and propeller installation information. It utilizes code from two previously developed propeller noise prediction programs: NASA's WOBBLE prediction code³⁸ and the Federal Aviation Administration's (FAA's) V/STOL propeller noise prediction program.^{39–42} These computer prediction codes were modified and integrated along with a graphical user interface to produce PACE. The result of this effort is a PC-based program that can be used without the need for an in-depth understanding of aeroacoustics.

The PACE model has some limitations. First, the model does not include the effects on noise of nonuniform inflow generated by the nose of the aircraft in tractor installations or the disturbances of the wing and other aircraft surfaces on flow into pusher propellers. Nonuniform inflow can produce higher noise levels than uniform inflow, so PACE may produce lower predictions than actual noise levels. Second, the noise levels produced by the PACE model include only propeller noise and exclude other noise sources such as engine noise. As propeller rpm is reduced, the aircraft's engine may become a more significant contribution to the total aircraft noise. Third, the model does not include the noise created by interactions of ground vortices or atmospheric turbulence with the propeller. This would result in predicted noise levels less than actual noise levels at flight speeds below 35 kt (particularly at static conditions). Finally, the PACE model does not include a method for predicting nonlinear effects that occur when the propeller speed nears sonic conditions. Under conditions where the combination of flight and rotational Mach numbers approaches the speed of sound, the predicted noise levels will be less than the actual noise levels.

6.3.2 General Aviation Integrated Noise (GAIN)

Method The GAIN computer program was developed in a NASA/FAA/industry funded program to predict the flyover noise of general aviation aircraft. It was completed in August 2001 and will be available to the public in August 2006. It is PC based and includes the capability to predict propeller performance and noise and intermittent combustion piston engine noise. It is a fairly complete user-friendly method. The following discussion on the various modules of the GAIN code are based on information from the users manual.³⁸

The performance module of GAIN is designed to predict propeller blade loading and overall performance at normal operating conditions. The code can be used for either fixed-pitch or constant-speed (variable-pitch) propellers. It contains airfoil data for Clark-Y, NACA 4-digit, and NACA 16-series airfoils and is capable of calculating unsteady lift coefficients due to angular inflow to the propeller and/or installation flow fields. The code can be run for an isolated propeller, a propeller at an inflow angle in either the pitch or yaw direction, or a propeller in an aircraft flow field. The user can select between seven built-in aircraft flow fields or provide a separate file containing aircraft flow field data.

Thickness and loading tone noise predictions are made by use of a program based on the frequency-domain approach of Hanson.³⁹ The theory utilizes the thickness and loading terms of the FW-H equation for a uniformly moving medium. The analysis incorporates the influence of angular inflow, due to aircraft angle of attack (pitch and yaw) or due to the aircraft installation flow field. In the presence of angular inflow, both the monopole and dipole source distributions are unsteady in the propeller reference frame, due to varying blade section relative speed.

Propeller quadrupole tone noise predictions in GAIN are based on the time-domain approach of Brentner.⁴³ The theory utilizes the quadrupole term of the FW-H equation and requires numerical evaluation of source integrals over a volume surrounding the propeller blade. After calculation of the time-domain pressure field, a Fourier transform is used to extract the frequency components of the radiation field. Quadrupole effects are typically fairly small for general aviation propellers so a number of approximations in the quadrupole source modeling have been made in GAIN. The quadrupole module is included in the GAIN program to provide the user with an option for assessing the importance of quadrupole source effects, for situations where they might become important (such as cases involving high subsonic relative Mach numbers near the tip of the propeller blade).

The broadband noise source that is modeled in GAIN is the interaction of the boundary layer turbulence with the trailing edge of the propeller blade. The code is based on the analysis of Amiet and Schlenger^{44,45} in which the boundary layer turbulence is assumed to produce a "frozen" pressure field that convects past the trailing edge. The frozen pressure field of the boundary layer turbulence is represented by an empirical model. Linear acoustics theory is used to calculate the sound radiated by the interaction of this frozen pressure field with the trailing edge. Additional information on this can be found in Ref. 9.

The engine on an aircraft produces noise that may be significant in aircraft flyover measurements. GAIN provides aircraft intermittent combustion (piston) engine tone and broadband noise predictions. The approach is an empirical method based on interpolation of a database of experimental measurements of engine noise spectra. The user can select one of three

Figure 3 Measured and PACE-predicted one-third octave band spectra of aircraft flyover noise level.

engine options: Lycoming O-320 D1D, Lycoming O-360 A-series, or Lycoming O-320 D1D with Cessna 172 Standard Muffler. Additional information can be found in Ref. 25, 46, and 47. After execution of the noise source modules, the GAIN postprocessor module applies noise propagation effects (Doppler factors, spherical spreading, atmospheric attenuation, and ground reflection) to each noise source.

Validation studies have shown that the GAIN predictions agree quite well with high-quality flyover noise measurements. Figure 3 shows the agreement for measurements of a typical general aviation aircraft. The one-third octave band spectra are those that occur when the highest A-weighted noise level occurs. The importance of engine noise in accurate prediction of aircraft flyover noise can be seen in Fig. 3. It can be seen that the tones that are indicated by three spikes in the spectrum below 500 Hz are in reasonable agreement with the measured peak in the spectrum. However, above 500 Hz, the agreement between the propeller alone prediction and the measurement becomes greater with increasing frequency. If the engine noise prediction is added to the propeller noise prediction, it can be seen that the agreement with the measured spectrum is quite good. The corresponding overall noise level and the A-weighted noise level for the measured and predicted spectra are also in good agreement. This good agreement has been found in many other comparisons of GAIN predictions with general aviation propeller aircraft flyover measurements.

6.4 Computational Fluid Dynamics–Based Computational Aeroacoustic Method

Because of the advances in computational fluid dynamics (CFD) and availability of powerful digital computers, the calculation of propeller noise in the near field is now feasible by this method, which is now known as the CFD-based computational aeroacoustic (CAA) method. Such a methodology is based on very

sophisticated turbomachinery codes. This approach is computer intensive. One of the chief advantages of this method is the capturing of the nonlinear effects that can be important for highly loaded high-speed propellers operating in asymmetric flow fields. However, it must be emphasized that the accuracy of most unsteady turbomachinery codes deteriorate with distance from the propeller. Therefore, the best one can hope for is the accurate prediction of unsteady surface pressure on the fuselage that is the cause of aircraft cabin noise. Lim et al.¹⁴ have demonstrated that near-field noise can be accurately predicted using this approach. Since the other time-domain and frequency-domain methods described in this chapter produce quite accurate results and are much less computer intensive, computational aeroacoustic methods are not often used for conventional propeller noise studies. However, for high-speed propeller noise prediction, coupling this method in the near field to the FWH equation with penetrable data surface for radiation calculation appears to be an ideal and highly accurate method of noise prediction.

7 METHODS OF CONTROLLING PROPELLER NOISE

The major objective in controlling propeller flyover noise is to meet the level required for certification. Propeller noise is the natural result of the production of the thrust required to permit an aircraft to fly. Both experimental and analytical studies have been conducted for many years to establish methods to reduce propeller noise while maintaining the thrust required for aircraft flight. The most beneficial elements of noise reduction are: reduce propeller rpm, reduce propeller diameter, increase the number of blades, reduce the blade width, thin the blade airfoils particularly near the tip, and use a round or elliptical blade tip rather than a square tip. Other elements of noise reduction are: blade planform

sweep and unequal circumferential blade spacing. Further discussion of propeller noise reduction technology can be found in Ref. 9 and 48.

It should be noted that there are penalties for reducing rpm to reduce noise. For a given engine reducing rpm reduces power. If power is maintained at the lower rpm by using a larger engine, there will be a cost and weight impact.

The reduction of propeller and propfan noise at high-speed cruise was the subject of considerable research in the 1980s. Blade sweep was found to be beneficial in reducing cruise noise reaching the fuselage.⁴ Reductions of about 5 dB were found in tests comparing noise produced by unswept and swept blade propellers.

Noise of counterrotation propellers consisting of two blade rows rotating in opposite direction has been addressed by Hanson. He showed that, in addition to the noise sources of single-row propellers, noise due to acoustic and aerodynamic interference must be included in predictions of counterrotation propellers.

Experimental programs have been conducted over the years in attempting to find the propeller modifications that reduce noise. However, the benefits of changes in configuration were difficult to quantify because of the cost of building and testing a sufficient number of propellers with systematic variations in configuration. For example, the experimental program conducted by Dobrzynski and Gelhar¹⁷ where the number of blades was incrementally increased from two to six used propellers that did not have systematic differences. As the number of blades increased by one, the diameter was reduced by 5%. However, blade geometry for the different propellers was not changed in a consistent manner due to cost constraints in the program. Figure 1, based on information from Ref. 17, confirms that increasing blade number while reducing diameter reduces noise. With this set of data it was also shown that increasing the number of blades to more than four did not further reduce the measured noise. However, the predicted noise continued to be reduced as number of blades was increased. This was attributed to a level of engine noise, which prevented the reduction in propeller noise to be observed.

The cost and complexity of the test programs such as that described above can now be overcome by use of computer-based noise predictions. Even though the strategy for reducing propeller noise involves complex trade-offs, these can now be addressed with user-friendly PC-based computer programs with remarkably accurate results.

Reference 49 summarizes a systematic analytical study to determine the noise reduction potential of increasing the number of blades. This study made use of the PC-based PACE method described elsewhere in this chapter. The reference for this study was a two-blade variable-pitch propeller. The effect on noise of (1) increasing the number of blades to three and four, (2) reducing the blade width as the number of blades was increased, and (3) reducing diameter was evaluated. The study addressed the fact that reducing the diameter of a propeller at a given rpm increases slipstream velocity. This increase in velocity increases

aircraft drag. This increase in drag was calculated for each diameter studied to keep aircraft performance constant. All of the blade geometric characteristics used in the study were based on a single generalized configuration contained in PACE. The propellers with the highest blade width that met the required thrust were identified. These configurations are the most likely to meet structural requirements.

The results of the study showed that increasing the blade number from two to three and reducing diameter by 9% (while reducing blade width) reduced the A-weighted noise level by about 13 dB. Increasing the blade number to four was found to be unacceptable as the required thrust could not be achieved. It should be noted that the noise reductions predicted do not include the influence of engine noise because the PACE program does not include engine noise. Reducing the blade airfoil thickness near the blade tip and rounding the square tip reference blade was found to reduce noise in some cases by less than 2 dB. It should be noted that the effect of the interaction of the propeller with the flow field induced by the nose of the airplane is not included in PACE. This interaction has been found to be important in studies using the GAIN program described elsewhere in this chapter. Also, the added tone noise caused by torque impulses generated by engine firing are not a part of PACE so could not be included.

It should be emphasized that the structural acceptability of the configurations of the above study were not established, so it is not likely that the full A-weighted noise level reduction of 13 dB can be achieved in a production configuration. Furthermore, as propeller noise is reduced, the noise of a typical piston engine will become more significant in the total peak aircraft flyover noise, thus limiting the noise reduction that can be achieved. Repeating the above study using the GAIN code (which includes the flow field effects and the engine noise contribution) and establishing the structural limits for promising configuration changes would provide practical guidance for reducing general aviation aircraft flyover noise.

CHAPTER 91

HELICOPTER ROTOR NOISE: GENERATION, PREDICTION, AND CONTROL

Hanno H. Heller and Jianping Yin

German Aerospace Center (DLR)

Institute of Aerodynamics and Flow Technologies (Technical Acoustics)
Braunschweig, Germany

1 INTRODUCTION

Helicopters are highly versatile flight vehicles. They can fly straight ahead, land and take off vertically, and even fly sideward and backward. Their most distinctive capability is that of hovering. Almost no other aircraft can do all that in a controlled manner (the vectored thrust Harrier is a notable exception in the fixed-wing realm). These singular “talents” are made possible by the helicopter’s unique lifting and propulsion systems (including its tail-rotor-related antitorque system), but are, however, accompanied by very complex aeroacoustical phenomena on the rotors with inherent and equally complex noise generation and radiation mechanisms. Although rotor noise usually dominates, there are helicopters where engine noise could prevail.

To appreciate the complexities of rotor aeroacoustics, this chapter starts with a discussion of *rotor kinematics*, followed by an elaboration on *rotor source characteristics* with emphasis on impulsive types (high-speed impulsive and blade–vortex interaction impulsive noise). The subsequent section deals with *theoretical aspects of rotor noise prediction* featuring Lighthill’s acoustical analogy, integral formulations [such as Ffowcs Williams and Hawkins (FW-H) and Kirchhoff formulations], and computational aeroacoustics (CAA) methods. The chapter concludes with description of *rotor noise reduction measures*, specifically active reduction of blade–vortex interaction noise, passive reduction of high-speed impulsive noise, and reduction of tail rotor noise.

2 ROTOR KINEMATICS

Unlike on fixed-wing aircraft, the entire lift (upward pushing force to raise the helicopter’s mass) as well as the propulsive thrust is solely generated by the main rotor utilizing a highly complex blade control system. A helicopter main rotor can be considered a “rotating wing.” Under conditions of forward flight, the tip of that rotating wing (i.e., the rotor blade tip) experiences high speeds on the “advancing side” of the rotor azimuth due to the combination of the rotor rotational speed (e.g., 220 m/s at the tip) and the flight speed (e.g., 50 to 80 m/s), as can be seen in Fig. 1. Since these two speeds simply *added* together, the blade tip at and around the azimuthal angle of $\psi = 90^\circ$ sees “incoming flow” speeds between, say, 270 and 300 m/s. A fraction of a second later, that same tip

on the “retreating side” of the rotor azimuth (i.e., near $\psi = 270^\circ$) is exposed to lower flow speeds, of, say, between 140 and 170 m/s, because now the flight speed is *subtracted* from the tip speed.

If the blade pitch (i.e., the geometrical angle of a blade with respect to the rotor plane) stayed the same, then the lift, which the rotating wing provides, would vary dramatically during a rotor revolution. The helicopter would tend to wobble around. The technical answer is to control that flow angle of attack in such a way as to attain low values on the advancing side and higher ones on the retreating side, with smoothly varying values in between.

This is achieved by controlling the kinematic motions of the rotor blade. While spinning around, a rotor blade executes *flapping motions* (vertical to the rotor plane), *pitching motions* (about the blade axis), and *lead-lag motions* (in the rotor plane). For these three motions bearings or hinges at the blade root are required. These are mechanically quite involved. Many of the heavier helicopters feature bearings and thus articulated rotors. For light- and medium-weight helicopters, some manufacturers employ flexible hinges (semirigid rotors), thus taking advantage of elastic elements at the blade roots and the thereby possible “natural” flapping (and other) motions of the blades, depending on the equilibrium of the acting forces: lift, weight, centrifugal, and other accelerating forces.

On the *advancing* side, the elastic blade tends to move upward. This induces a vertical flow speed component such that the effective flow angle of attack is slightly reduced, causing a reduction in the lift—which is the desired effect. On the *retreating* side, the enormous centrifugal forces (some 20 tons!) pulling outward on the blade tips reduce the local coning angle, which increases the effective flow angle of attack, resulting in higher lift—which, again, is the desired effect. In this way, the lift across the rotor plane remains, inherently so to speak, fairly uniform.

To attain forward speed, the blade pitch must be actively increased on the rear arc (i.e., near $\psi = 0^\circ$) and decreased on the forward arc (i.e., near $\psi = 180^\circ$). This way, more lift is generated at the rear and less at the front, thus pushing the nose of the helicopter down; the rotor now blows air slightly backward and downward thus driving the helicopter forward.

To actually affect the blade pitch, the pilot through his control inputs changes the tilt of the swash plate on the rotor hub (Fig. 2). A typical swash plate may

Figure 1 Aerodynamics and acoustics of rotor during high-speed straight level flight.

Figure 2 Main rotor head kinematics.

consist of a lower *stationary* portion whose motions are mirrored by the upper *rotating* portion, which in turn is linked to the leading edge of each blade. Thus, by acting on the swash plate, the pilot is able to control the pitch of the blades as they rotate. A swash-plate tilt with respect to the rotor shaft results in up and down motions of the blade control rods. The blade pitch then follows these sinusoidal control rod motions, affecting the blade lift and, thus, the blade flapping motions (with a certain phase delay depending on the blade stiffness), up during one half of the rotation, down during the other. This way, the pitch of the rotor blade could be lower in the forward arc and higher in the rear arc to result in forward flight. The opposite would be the case for a backward flight. Likewise, sideward flights to the left or the right could

be controlled by appropriately changing the tilt of the swash plate. Pushing the entire swash-plate assembly up or down (rather than tilting it) would simply cause a simultaneous pitch change of all blades by the same amount across the rotor plane, resulting in an upward or downward flight without any horizontal movement.

The tail rotor—while preventing the helicopter to turn in the opposite rotational direction of the main rotor—is also instrumental for position control in sideward flights, turns, and the like. Most importantly, the tail rotor counteracts the moment of the main rotor. The thrust of the tail rotor is adjusted such that it exactly compensates that main rotor push, thus allowing the helicopter to fly straight ahead. A tail rotor experiences “dramatic” inflow changes similar to those occurring on the main rotor in that its forward-moving blade tip “sees” high speeds and the backward-moving blade lower speeds. The tail rotor also operates in the shed aerodynamic wake of the upstream main rotor and also in the wakes of the main rotor hub and of the fuselage. The flow conditions near and around a helicopter tail rotor are extremely complex. Therefore prediction of tail rotor aerodynamics and noise is likewise an extremely complex problem, which presents a major issue for designers.

3 ROTOR NOISE GENERATION

Sources of helicopter noise are its main rotor, its tail rotor, the engines, and the drivetrain components. The dominant noise contributors though are the main rotor and the tail rotor since they operate in the

Table 1 Classification of Rotor Noise

Physical Mechanism	Acoustic Source Type	Spectral Character	Rotor-Specific Noise Type
Volume displacement Nonlinear effects (predominantly at high blade tip Mach numbers)	Thickness noise Noise from periodic shock separation	Discrete frequency Discrete frequency	Impulsive noise HS impulsive noise
Rotating blade forces	Deterministic loading noise	Discrete frequency	Rotational noise
Blade–vortex interaction (BVI) (predominantly at moderate speed descent)	Deterministic loading noise	Discrete frequency	BVI impulsive noise
Turbulent inflow, blade–wake interference, flow separation	Nondeterministic loading noise	Stochastic	Broadband noise
Main rotor wake–tail rotor interaction (specifically main rotor tip vortex–tail rotor interaction)	Deterministic loading noise	Contains discrete frequency and stochastic components	“Periodic” broadband noise

free atmosphere and thus radiate noise unobstructedly into the surroundings. Engine noise often plays a lesser role, although for large helicopters engine noise could dominate at takeoff. Rotor noise including main rotor and tail rotor noise can be classified into discrete-frequency rotational noise, broadband noise, and impulsive noise (also of discrete-frequency character), as shown in Table 1.

Accordingly, rotational noise comprises *thickness noise* (i.e., noise generated from the periodic volume displacement by the rotating blades) and *loading noise* (rotating lift and drag forces). The former is more important in the low-frequency range of the rotor noise spectrum (i.e., at the blade passage frequency and first few harmonics, but it contains mid-, and

high-frequency components too, being of impulsive-type nature). At low rotational speeds and for low blade loading, the thickness noise line spectrum can be exceeded by the *broadband noise* components. Broadband noise is a result of turbulent inflow conditions, blade/wake interferences, or even blade self-noise (“airframe noise”).^{1–6}

Of greater importance are *impulsive-type noise sources*, resulting in the familiar “bang, bang, bang” sound. Of these, there are two kinds: High-speed (HS) impulsive noise and blade–vortex interaction (BVI) impulsive noise. As shown in Fig. 3 (flight envelope: climb–descent rate vs. flight speed diagram), the former appears predominantly at high flight speeds, independent of the climb or descent rate, while the

**Figure 3** Helicopter operational flight envelope.

Figure 4 Pressure amplitude time history signatures and corresponding sound pressure level spectra for high and low tip speeds.

latter occurs predominantly during moderate speed descent. Tail rotor noise has almost all characteristics of main rotor noise. The flow around the tail rotor is the sum of the interacting flows generated by the wakes of the main rotor, the fuselage, the rotor hub, as well as the engine exhaust and empennage flows in addition to its own wake. It is known for most helicopters that tail rotor noise dominates at moderate speed straight flight conditions and during climb, though. Tail rotor noise broadband component are of low levels and need not actually be considered. As mentioned above, engine noise could dominate for some helicopter during takeoff as discussed in Refs. 7 and 8.

3.1 Main Rotor High-Speed (HS) Impulsive Rotor Noise

A rotor blade is not infinitely thin but has a finite thickness. Also, its chordwise surface profile is curved, probably more so on the upper surface than on the lower surface. As the air over the upper curved surface moves faster than over the slightly lesser (or not at all) curved lower surface, the *difference* in pressure (lower pressure on top, higher pressure on the bottom) provides the wanted upward suction, or lift.

For conditions of high-speed forward flight, this increase in speed on the upper curved surface may now result in the surface M_{AT} (advancing tip Mach number) to assume values *above* 1, even if the “local inflow Mach number” toward the blade was only 0.9. That is, that Mach number is slightly supersonic, however, only for the *very short* time span, when the blade moves through the “advancing side rotor azimuth” near

$\Psi \approx 90^\circ$. When this occurs, an aerodynamic shock appears in the flow immediately above the upper blade surface. The supersonic flow above the blade surface suddenly—across a shock front—assumes subsonic values: upstream of the shock front local flow speeds are supersonic, behind the shock front they are subsonic with a sudden steep pressure rise. The sudden appearance (and disappearance) of such an aerodynamic shock on the blade causes an impulsive sound signal (Fig. 4). For a four-bladed rotor, for example, which spins around 5 times a second, 20 such impulses (“bangs”) per second would occur. The phenomenon is termed *high-speed (HS) impulsive rotor noise*.^{9–15} HS noise is most strongly radiated into the forward arc, that is, the flight direction, and roughly along the rotor plane—not much above and not much below. Thus, HS noise is heard when a helicopter approaches from far away; once the helicopter is overhead, HS noise disappears and loading noise, and/or tail rotor noise, tends to dominate.

For lesser flight speeds, when advancing tip Mach numbers, M_{AT} , are lower (say below 0.85 or so) and in the absence of HS noise, loading noise and thickness noise take over acoustically. Loading noise has a maximum in a downward (and upward) direction. Hence, when the helicopter flies overhead, one hears its characteristic “thud/thud/thud” noise.

3.2 Main Rotor Blade–Vortex Interaction (BVI) Impulsive Noise

When a blade (a lifting surface) moves through the air, a strong vortex is shed from its tip. The vortex trail shed from the tip of a rotating blade assumes

Figure 5 Epicyclical tip vortex trails and interaction of blades.

Figure 6 Blade-surface pressure coefficient patterns and resulting radiated acoustics one rotor radius below rotational plane (from DNW experiments) for conditions of strong blade–vortex interaction (BVI) employing a model B0105 main rotor.

an epicyclical pattern. A subsequent rotor blade may collide with such a vortex (Fig. 5), causing sudden local velocity changes, and, hence, local lift changes. Conditions for such collisions occur invariably during descent flights at moderate speeds (typically at flight speeds of 25 to 50 m/s and descent angles of 5° to 8°). Under these circumstances, the vortex trails are sucked into the rotor plane to cause a sequence of multiple interactions, each time a blade hits a vortex trail. This phenomenon, BVI impulsive rotor noise, is discussed in Refs. 16–24. The intensity of BVI impulsive noise depends on the ratio of flight and descent speeds, that is, on the flight angle and the through-flow through the rotor plane, or, conversely, on the tip path plane angle and the advance ratio (ratio of flight and blade

tip speeds); it grows with thrust coefficient and blade tip Mach number.

From the kinematics of BVI (as illustrated in Fig. 6 from wind tunnel results on a model main rotor), it becomes evident that such strong interactions would occur in the first rotor quadrant (near $\Psi \approx 45^\circ \pm 20^\circ$) on the advancing side, where a blade's leading edge would encounter the vortex trail in a parallel manner and, thus, over a fairly extended radial blade span, with the consequence of a very strong impulse. The same would be the case at the fourth rotor quadrant (near $\Psi \approx 315^\circ \pm 20^\circ$) on the retreating side, where, again, the interaction would occur over an extended regime of the leading edge. In contrast, near the second quadrant ($90^\circ < \Psi < 180^\circ$) and the third quadrant ($180^\circ < \Psi < 270^\circ$), interactions would be a very localized event

over a very small extent of the blade leading edge, thus causing a very weak acoustical signal. Hence, one speaks about *advancing side BVI* and *retreating side BVI*.

Blade–vortex interaction noise differs in its acoustical directivity compared to HS noise. Wind tunnel research has shown that advancing side BVI radiates most strongly in a forward/downward direction (roughly 45° to 60° down from the rotor plane) while retreating side BVI exhibits its directivity peak in a downward/backward direction, again roughly 45° to 60° down from the rotor plane.

3.3 Tail Rotor Noise

Although the tail rotor operates in the strong wake of the main rotor (of particular importance being the interaction of the tail rotor with the tip vortices shed by the main rotor blades) and of the fuselage, certain aeroacoustical features are quite similar to those of the main rotor.

The main acoustical components are again thickness noise (especially on high-speed tail rotors) and loading noise. Furthermore, the combination of flight speed and tail rotor rotational tip speed may result in locally transonic inflow speeds, again causing the appearance of shocks and the associated acoustical events. Also, the impingement of the main rotor wake flow onto the tail rotor may cause blade–wake interactions with impulsive sounds to occur. The periodicity of this interaction noise may be one per main rotor revolution when the ratio of the rotor revolutions/minute (rpm) between main rotor and tail rotor is an integer number instead of one per tail rotor revolution for self-generated tail rotor BVI noise. Due to this source's largely forward/upstream directivity, it can often be detected well ahead of the approaching helicopter, although directivity details may depend on the relative position of the tail rotor and the main rotor. Tail-rotor-related thickness noise exhibits a directivity downward (and maybe upward), clearly detectable when the helicopter flies overhead. In general, though, tail rotor noise is heard under conditions of straight level flight or climb, that is, when the strong main rotor BVI noise components (occurring only under descent flight conditions) are inherently absent. For a helicopter in descent flight, the tail rotor noise would be drowned by the main rotor BVI noise. But as said, a tail rotor may also generate its own BVI noise.

In some light- to medium-weight helicopters the open tail rotor is replaced by a fan-in-fin or “fenestron.” Rotor stator interactions must then be considered along with sound wave scattering on the duct lips. Tail rotor noise is discussed in Refs. 25 to 27.

4 ROTOR NOISE PREDICTION

Several modern approaches have been developed to predict helicopter rotor noise, known under the designations *Lighthill's acoustical analogy* (aeroacoustical source terms), *integral formulations*, such as *Ffowcs Williams and Hawkings*, *FW-H*, as well as *Kirchhoff formulations* (as part of using aerodynamic field information hybrid methods), and *computational*

aeroacoustics (CAA) (use of aerodynamic methods for direct noise calculations). CAA methods are designed to accurately capture the unsteady flow and noise radiation, but, presently, solving acoustical problems involving “three-dimensional rotors” by means of CAA is still too expensive and impractical. Therefore, integral formulations, such as FW-H and Kirchhoff formulations, are still very useful for the purpose. A general schematic of alternative rotor noise prediction approaches appears in Fig. 7.

To predict rotor noise, say in terms of sound pressure time histories at an observer point, noise may be broken down into three source types occurring on a rotor, namely thickness noise, loading noise, and compressibility noise.

Hence, the acoustical analogy approach utilizes three corresponding aerodynamic source terms: the linear thickness noise term (with the characteristics of an aerodynamic monopole), the linear loading noise term (with the characteristics of an aerodynamic dipole), and the non linear compressibility noise term (with the characteristics of an aerodynamic quadrupole) as inputs into appropriate acoustical codes, such as the FW-H formulation,^{28,29} which in turn is based on the classical Lighthill formulation of aerodynamic noise.³⁰

The *monopole source term* can be computed solely from information on blade geometry and kinematics, the latter depending on rotor operational conditions. The *dipole source term* can be determined in several ways. One approach is based on inviscid potential flow methods, such as *lifting line* or *lifting surface theory*, or *unsteady panel methods* based on singularity theory to yield, respectively, high-resolution unsteady blade loadings or high-resolution unsteady blade pressures. Another approach to determine the acoustic dipole source term is based on solutions of *Euler equations*, which, again, provide high-resolution blade pressure information. The characteristics of the inviscid potential flow methods are as follows:

- In *lifting line theory* (see Ref. 31) the lift is considered to be generated by a single (“bound”) vortex filament at the blade quarter chord along the blade span. Pressure equalization at the blade root and tip generates root and tip vortices. Blade rotation and forward motion cause these “wake” vortices to follow a complicated epicyclic path to constitute the wake. Often this vortex wake is taken as time invariant (“prescribed wake”), although it is presently fully recognized that a free wake model must be included into the lifting line code, as must the elastic properties of the blade, to arrive at better simulations. The output of the calculation is only the lift distribution over the blade span as input into the acoustical codes, without regard to the details of blade planform, tip shape, profile, and the like.
- If the lift variation over the chord is of importance, the *lifting surface method* (see Ref. 32) accounts for it with a distribution of lifting lines over the blade chord. The

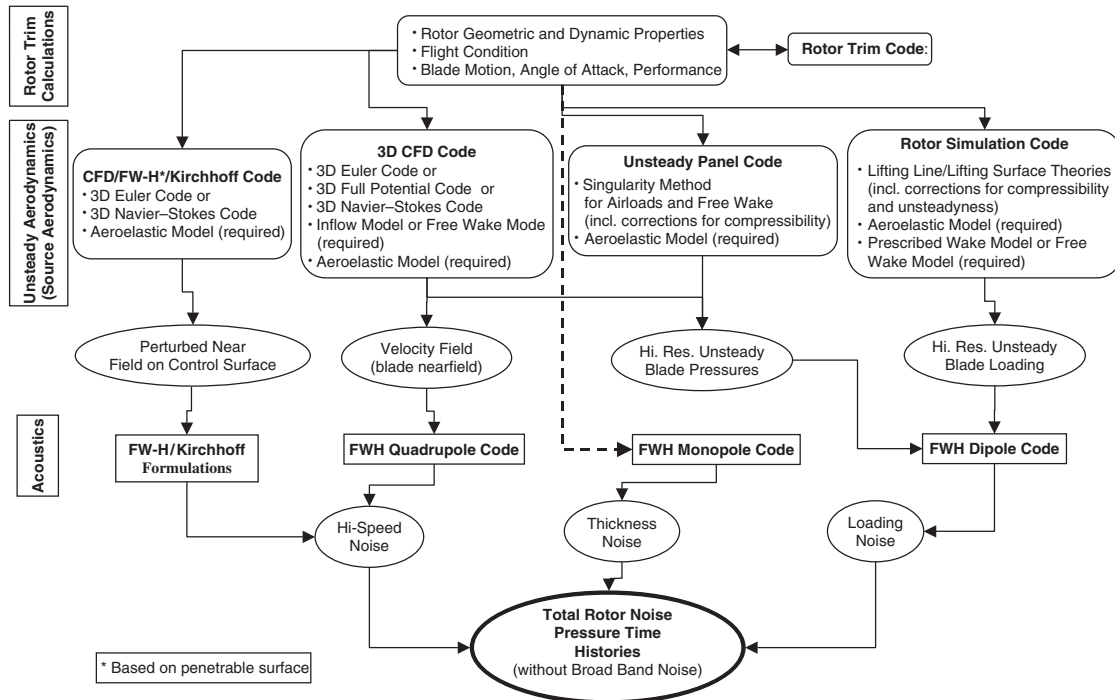

Figure 7 Helicopter rotor noise prediction schematic (alternative methods).

concept allows for both including or neglecting blade thickness as the distribution is spread over a blade chord. Thus, nonrectangular blade planforms with twist and blade tip modifications can be simulated and the ensuing pressure data be used as input into the acoustical codes.

- *Unsteady panel methods in combination with free wake model* (see Ref. 33) permit the modeling of the aerodynamics of the rotor and especially the aerodynamic interactions among the rotors.³⁴ In essence, all geometric parameters of a real blade (profile geometry, planform, twist, tip shape, etc.) can now be accounted for. The calculations yield the pressure and velocity distribution on the upper and lower blade surfaces. Accordingly, a more realistic simulation of blade geometry and, correspondingly, more detailed aerodynamic information is available as input for the acoustical codes.
- The alternative method to arrive at the dipole source term is to compute the acoustic near-field blade pressures by means of an *Euler solver*. Blade loading is evaluated by integrating the pressure over the surface grid of the blade used for the aerodynamic computations (see Ref. 35). This method inherently accounts for the blade's geometrical details.

Linearized potential flow methods to compute the dipole source term need only moderate computation

time and are well suited for application in prediction schemes of rotor noise for blade tip speeds well below those where major supersonic flow regions on the blade would appear, that is, at low to moderate forward speeds. Their inherent drawback is their inability to account for compressibility effects as needed to compute the *quadrupole source term*. At higher speeds, though, the quadrupole source term must be included, even if only in an approximated form, once supersonic flow regions and shocks near the blade tip appear during forward flight (see Ref. 36).

Treatment of such nonlinear effects is the domain of "field methods" such as *full potential* or *Euler methods*.³⁷ If the rotor is encompassed by a shock, the quadrupole field must be accurately evaluated through appropriate volume integration procedures. This, however, is a very involved process.

Here, the *combination of computational fluid dynamics (CFD) and Kirchhoff methods*³⁸ is to determine the near-field aerodynamics by means of full potential or Euler/Navier–Stokes equations, accounting for all nonlinear compressibility effects, which are then integrated onto the Kirchhoff surface. The Kirchhoff surface should completely surround the rotor at an appropriate distance. Starting from that surface around the nonlinear near field of the rotor, computation of the subsequent sound propagation into the far field requires only linear equations.

Hence, the Kirchhoff surface divides the flow region into an inner part where nonlinear effects prevail (and where the flow solution is obtained by solving the Euler equations) and an outer part where linear acoustic wave propagation prevails. This combination of the Euler and Kirchhoff methods provides better agreement of measurements and prediction than the direct computation of the acoustic far field solely by means of an Euler approach.

The combination of CFD and the FW-H formulation based on penetrable surface (P-FW-H)^{39,40} represents a more appropriate and, in fact, more flexible technique to compute the acoustic radiation at high tip speeds for conditions of hover or level flight compared to the Euler–Kirchhoff approach. The reasons are:

- The Kirchhoff solution is very sensitive on the location of the integral surface because the Kirchhoff method requires placing the integral surface in the region where the flow is completely governed by a homogeneous linear wave equation.
- Current CFD simulation could only support information that is close to the source region, where nonlinear effects cannot be avoided. The error due to nonproper location of the Kirchhoff surface can be large, especially if the integral surface is positioned in the nonlinear region, even if in a slightly nonlinear region.
- P-FW-H has all the advantage embedded in the Kirchhoff formulation and is valid even if the integration surface is located in the nonlinear region and the region containing vorticity so that it is less sensitive to the placement of the integration surface.
- Input quantities are directly available from CFD codes, which is not the case for the Kirchhoff formulation.

In summary, then, (a) linearized inviscid potential flow methods in combination with the acoustical analogy approach and (b) analyses using Euler results in combination with acoustical analogy approaches are suitable for rotor noise predictions at low to moderate tip speeds. For high-tip-speed cases, including those where shock delocalization occurs, CFD and FW-H and Kirchhoff approaches may be better qualified. Here, the CFD-based computationally expensive flow-field calculations are confined to the near-field inside the FW-H and Kirchhoff surface where nonlinear effects prevail. Prediction of the far field sound pressure field can be realized with the FW-H and Kirchhoff surface integration.

Predicting the noise of a helicopter already in the design stage is thus a rather involved undertaking. While it might be possible to predict the noise from an isolated main rotor, already accounting for the realistic fuselage refraction effects adds another level of complexity. Even more complicated would be the computation of the interaction effects of main and tail rotor unsteady aerodynamics/acoustics to arrive

at a viable far-field noise prediction. Often empirical or semiempirical prediction schemes are employed, based, for example, on flyover noise measurements from which the noise for different specific flight conditions (takeoff, low-speed and high-speed level flight, and climb flight) are determined. From these the directivity pattern on a fictitious hemispherical surface around the helicopter (e.g., at a radius of 100 m) is derived. This “acoustical directivity hemisphere” is then “flown over the landscape,” to obtain a (fairly accurate) acoustical footprint for the helicopter under consideration. But already extrapolating these findings toward another helicopter is quite uncertain.

A rough indication of the noise of helicopters may be obtained from noise certification data, as published by the national aviation authorities. Here, albeit for very specific flight conditions, the overall, weighted noise levels are available. Such data can be—with limitations—also used for land-use planning purposes.

5 ROTOR NOISE REDUCTION

Reducing rotor noise really constitutes a balancing act. As in any noise control effort, different noise sources need to be “equalized” such that none dominates above the other. In the case of a helicopter, there would be a need to balance the relative noise levels of main rotor and tail rotor, including the interaction sources (and in some cases engine noise). Corresponding considerations are important in the design of a quiet helicopter. For a helicopter, of course, there is the added complication that different sources dominate at different flight conditions.

5.1 (Active) Noise Reduction of Main Rotor BVI Noise

Blade–vortex interaction noise intensity can be reduced in three ways: (1) by decreasing the vortex strength (the maximum velocity near the vortex core) as such, (2) by minimizing the intensity of the very interaction process, and (3) by increasing the distance the vortex passes the blade, that is, the “miss distance” (Fig. 8). All this can be achieved, for example, by appropriately controlling the blade pitch “at the right moment” during the rotor rotation either by blade pitch control through the *higher harmonic control*, or HHC, technique or by the “*individual blade control*, or IBC, technique. The difference is that for HHC, the (additional) control actuators act on the “stationary” portion of the swash plate thus causing the identical blade-pitch variation on all blades during any rotor revolution, while for IBC, the actuators are attached to the rotating portion of the swash-plate, such that the pitch motion of each blade during any rotor revolution can be controlled individually. Evidently, the latter method offers greater flexibility. The two kinds of blade control are illustrated in Fig. 9. Only the IBC technique will be discussed further.

The above-mentioned BVI impulsive noise minimization methods are based on the following techniques:

Figure 8 Illustration of BVI noise reduction concept by means of blade higher harmonic control (HHC) or individual blade control (IBC).

1. The strength of a vortex as it separates from the blade tip is largely a function of the local tip speed and of the blade pitch. There is an optimum blade pitch that results in minimum vortex strength. If this "optimum" blade pitch could be attained just for the brief instant in time when that particular vortex is shed, which, one or two rotor revolutions later, interacts with a blade, then BVI noise should be less. Such, in fact, could be achieved by means of the IBC technique.

Normally, the blade pitch varies sinusoidally once per revolution (the cyclic pitch change). By means of the IBC technique, an additional

blade pitch variation of whatever waveform can be superimposed, so that the blade pitch, in addition to its sinusoidal cyclic pitch change, would experience changes of the desired kind (Fig. 10). Thus, the blade would locally change its pitch several times during a revolution rather than only once.

2. The very same technique can be utilized to effect the second of the above-cited noise reduction methods. If the blade pitch can be affected in any manner during each rotor revolution, one may also optimize its value for the same purposes during the very blade-vortex interaction process, that is, when the vortex comes into contact with a blade's leading edge, to thus minimize the local airload changes.
3. Finally, it should be possible to optimize the blade pitch during the vortex-shedding process as such so that the vortex, during the interaction process, passes the blade at some distance below or above, and not "square-on."* Alternatively, it should be possible to slightly change the path of the tip during the encounter such that the blade passes above or below the vortex.

The basics of these blade control techniques have been developed in the German Dutch Wind

*Actually, this is not quite correct since maximum BVI does not occur when the vortex cuts directly across the blade but at some, albeit very small, distance from it. But in any case, if the miss distance "vortex-to-blade" is made as large as possible, the interaction intensity is much reduced.

Figure 9 Active blade root control concepts.

Figure 10 Blade pitch angle variation during one rotor revolution when affected by an individual/arbitrary blade control input.

Figure 11 Ground signature noise reduction employing IBC versus baseline case (from flyover noise tests).

Tunnel, DNW, and later validated in flight tests on a real helicopter, a EUROCOPTER BO105, in a cooperative effort. Here, the “flight-worthy” actuators were installed above the swash plate and controlled in such a way as to achieve maximum noise reduction. The tests were successful: compared to the condition without blade control, the very BVI impulsive noise

was reduced by some 6 dB, that is, reduced by 50% (Fig. 11).⁴¹ IBC may also be favorably employed in reducing rotor blade vibrations. BVI noise reduction methods by the HHC technique are discussed in Refs. 42 to 44. A state-of-the-art survey on rotor noise reduction by means of harmonic or individual blade control appears in Ref. 45. BVI noise may, however,

also be passively reduced by means of appropriate shapes of the blade planform.^{46,47}

The most beneficial possibility for rotor noise reduction lies in cutting back the rotational speeds and to thus reduce the tip speed, but such a measure has adverse effects on the rotor stability and power, and even on the gears, by requiring a larger torsional momentum and perhaps incurring a weight penalty. However, helicopters featuring variable rotational speeds are being developed for this purpose.

An interesting method to reduce BVI noise has been proposed in Ref. 48. Here it is stated that for a given descent angle the rotor tip path plane angle can be increased through a “negative acceleration” (= deceleration). For a deceleration of 0.1g a significant reduction in BVI noise was observed. This beneficial effect is caused by the blades no longer directly intersecting the vortex trails. Technically, this could be achieved by some sort of an additional drag device during descent. In that case, the tip path plane angle corresponds to one at smaller descent angles without drag device. Hence a “clever” combination of the variables *flight speed*, *descent angle*, *deceleration*, and (perhaps) *added drag* can lead to a significant (BVI) noise reduction.

5.2 (Passive) Main Rotor High-Speed Impulsive Noise Reduction

There is no way to actively reduce high-speed impulsive noise. The only route is via optimization of the blades’ geometry and airfoil shape. The point is to try to avoid the appearance of an aerodynamic shock above the surface of the blade tip area.

For one, it would be advantageous to make a blade near the tip as thin as possible. Obviously, there are structural limitations to such an approach, the more promising way being the reduction of the local flow speed into the rotor blade along the outer span. An appropriate backward sweep should have the desired beneficial aerodynamic effect in minimizing the strength of the aerodynamic shock. Now the local inflow velocity component toward the blade’s leading edge is distinctly reduced, thus also reducing the supersonic area on the blade. This way, the occurrence of an aerodynamic shock is largely avoided. Wind tunnel tests have proven this technique, which represents the current state of technology, as many of today’s helicopters feature main rotor airfoil shapes of such kind.

While such a rotor blade planform would be desirable to reduce the noise during high-speed forward flight, it might actually be worse under descent flight conditions when it comes to BVI. Here the alignment of the blade leading edge and the vortex trace, if parallel, would cause maximum BVI impulsive noise. So, the art of a blade designer is to make a blade that (1) fulfills the performance requirements while (2) being quiet under *all* flight conditions, that is, both under conditions of high-speed level flight and of moderate speed-landing approach.

5.3 Tail Rotor Noise Reduction

Of the several measures to reduce tail rotor noise, the following will be mentioned: (1) reduction of rotational speed and hence tip speed; (2) utilization of many blades rather than only two, such as on the “fenestron”/“ducted fan” solutions, where the blade passing frequency is increased (this means that the generated sound is attenuated more by distance because of its higher frequency content, although this effect is counteracted by the higher auditory sensitivity of the human ear at frequencies around and above 1 kHz; sometimes uneven blade spacing is used); (3) changing the tail rotor sense of rotation and variation of tail rotor position with respect to the main rotor will eventually change the characteristics of tail rotor and main rotor wake interaction, which may induce some noise reduction; (4) shrouding the tail rotor, which increases its performance and allows lesser rotational speeds, albeit at the cost of additional weight, or even (4) elimination of the tail rotor altogether; the latter has been realized in the medium-weight American helicopter Explorer. The technique is called NOTAR (for “NO TAIL Rotor”). The physics behind the NOTAR approach is based on the Coanda effect/boundary layer control along the length of the tail boom, combined with the use of a direct jet thruster at the end of the tail boom. Unfortunately, this technique can only be used on smaller helicopters, as the weight penalty for such a device providing the required quite substantial amount of tail thrust on even a medium-weight helicopter is prohibitive. The means to reduce helicopter noise by use of a quiet tail rotor are discussed in Ref. 25.

6 CURRENT DEVELOPMENTS

New design helicopters, undoubtedly, will feature advanced blade geometries and airfoil characteristic shapes, inherently generating less noise and vibrations. New blade control techniques are developed to minimize noise and vibration, probably not so much by technically elaborate individual blade control techniques, but by employing *local* blade control techniques, where the shape of a blade in the tip area as such is dynamically changed by employing advanced piezoelectric devices embedded in the very blade surface. This would eliminate the need for elaborate and heavy actuators on the hub. Such novel techniques could also avoid early flow separation during high-speed and maneuvering flights, reducing additional power requirements. Ultimately, the entire conventional control system within the rotating system (control at the blade root or on flaps in the outer blade region) might become replaced by such elegant, light, and mechanically much less involved local control systems that act where they are needed, that is, in the outboard regime of the blade.

1 INTRODUCTION

Brake noise remains a concern throughout the automotive industry despite efforts over a number of decades to reduce its occurrence. The earliest work was on drum brakes but, as disk brakes gradually came into widespread use on cars and trucks, the focus of research shifted to these, as they have a much greater propensity to generate noise. The focus of many recent studies is on disk brake noise, the way in which a disk brake system generates noise, and current methods to reduce the noise. Comprehensive treatments of the subject are available in the literature.

2 BRAKE NOISE – A FUGITIVE PROBLEM

Problems with brake noise were reported as long ago as the 1930s. Since then much research work has been conducted; the reader is referred to reviews by Crolla and Lang,¹ Ionnidis et al.,² and Kinkaid et al.³ to gain an overview of the development of knowledge in this area.

A schematic of a disk brake is shown in Fig. 1. The disk is bolted to the wheel and axle and thus rotates at the same speed as the wheel. The calliper does not rotate and is fixed to the vehicle. Hydraulic oil pressure forces the brake pads onto the disk, thus applying braking forces that reduce the speed of the vehicle.

From the dynamics point of view, a braking system can be represented schematically as shown in Fig. 2, which depicts two dynamic systems connected by a friction interface. The normal force N is a result of the hydraulic pressure P and is related to the friction force F_f . It is the combination of the friction interface and the dynamic systems that makes the understanding and elimination of brake noise so difficult. As described in the next section, brake noise usually involves a dynamic instability of the braking system. Of course, brake systems are not manufactured to be unstable (as they would never sell) but many of them are conditionally stable systems that drift in and out of instability depending on operating conditions. A diagram depicting this situation is shown in Fig. 3.⁴ Because of this, brake noise has been described as being fugitive. Three overlapping “stability” parameters of friction, pressure,

Figure 1 Schematic of a disk brake showing the disk, brake pads, and calliper. This type of brake has a floating calliper.

and temperature are depicted (although there could be more, such as humidity). Within the area, marked “unstable,” changes to the parameters have little or no effect, and the brake has a high propensity to generate noise. Within the “conditionally stable” areas the brake would generally be quiet unless the operating conditions caused the system to move into the unstable area. Such conditions may be excessive cold or heat and a consequential change in the characteristics of the friction material. The stable area may be regarded as a well-designed brake, where the system may only move into the unstable region if there are dramatic changes in the system parameters.

Figure 2 Schematic showing a disk brake as two dynamic systems connected by a sliding interface of area S . The normal force N is a result of the pressure P and is related to the friction force F_f .

3 BRAKE NOISE CLASSIFICATION

Noise, vibration, and harshness (NVH) engineers classify brake noise and vibration using a variety of different words, such as *judder*, *groan*, *moan*, *hum*, *howl*, *squeal*, *squeak*, *sqelch*, *wire brush*, although none of these terms has a strict definition. In this chapter the types of vibrations/noise are grouped into three categories, which are chosen for distinct physical reasons.

Judder (around 10 Hz or Less) Judder occurs at the frequency of wheel rotation or a multiple of it. It is a *forced* vibration caused by non-uniformity of the disk and is generally felt rather than heard. There are two types of judder: cold judder. Cold judder is commonly caused by the brake pad rubbing on the disk during periods when the brakes are not applied. Hot judder is associated with braking at high speeds or excessive braking when large amounts of heat can

be generated causing transient thermal deformations of the disk.

Groan (around 100 Hz) Groan occurs at low speeds and is the first of the unstable brake vibrations. It is particularly noticeable in heavy goods vehicles coming to a stop and in automatic cars edging forward in a queue of traffic. It is thought to be caused by stick-slip behavior of the brake pads at the disk surface and the velocity dependence of the friction coefficient. The velocity dependence is because the dynamic coefficient of friction is lower than the static coefficient of friction.

Squeal (>1 kHz) Brake squeal is an unstable vibration caused by a geometric instability rather than a negative coefficient of friction–velocity slope. It is split into two categories; low frequency squeal (1 to 4 kHz), where the length of a brake pad is less than the length of the diametrical nodal spacing in the disk, and high-frequency squeal (>4 kHz), where the length of a brake pad is greater than the diametrical nodal spacing in the disk. A hologram taken by Fieldhouse,⁵ depicting the vibration of a squealing disk brake is shown in Fig. 4. The disk is rotating at 10 revolutions/minute (rpm), the squeal frequency is 10.75 kHz, and the nodal diameters are rotating about the center of the rotor at about 1344 Hz.

4 MECHANISMS OF NOISE GENERATION

Of the three categories of brake noise/vibration, judder is a forced vibration, and groan and squeal are unstable (self-excited) vibrations. Den Hartog⁶ distinguishes between forced and self-excited vibration as follows:

In a self-excited vibration the alternating force that sustains the motion is created or controlled by the motion itself; when the motion stops the alternating force disappears.

Figure 3 Diagram showing the way in which frictional, pressure, and temperature effects affect the stability of a disk brake system.

Figure 4 Vibration of a squealing brake.⁴ The disk is rotating at 10 rpm, the squeal frequency is 10.75 kHz, and the nodal diameters are rotating about the center of the rotor at about 1344 Hz.

In a forced vibration the sustaining alternating force exists independently of the motion and persists even when the vibratory motion is stopped.

Several mechanisms that cause dynamic instabilities in braking systems have been suggested and are described below.

Negative Friction–Velocity Slope This characteristic is illustrated in Fig. 5. At low speeds the dynamic coefficient of friction μ is related to the static coefficient of friction μ_{static} by $\mu = \mu_{\text{static}} - \alpha v_r$, where α is the gradient and v_r is the relative velocity between the pad and the disk. As mentioned above, this is thought to be the mechanism responsible for groan. In general, a viscous damping force is proportional to velocity. In a braking system with a low disk velocity, the action of the sliding interface is to act as a negative damper because the slope of the force–velocity graph is negative. Once the negative damping caused by the sliding interface exceeds the damping in either the brake or the pad system, self-excited vibration ensues, generating a noise.⁷ The amplitude of vibration is determined by the nonlinearities in the system such as a positive force velocity slope at high velocities, as shown in Fig. 5. To determine the amplitude of vibration of an unstable system, a full nonlinear analysis needs to be conducted. Because this is computationally expensive, it is rarely done in practice.

Sprag-Slip This mechanism for brake squeal was first proposed by Spurr⁸ and developed by Jarvis and Mills.⁹ They showed that it is possible for unstable vibrations to occur even when the coefficient of friction is independent of relative velocity between the pad and the disk. A simple illustrative model of a brake-disk system that behaves in this way is shown in Fig. 6. In this example, vibrations occur due to the constrained

Figure 5 Graph showing the relationship between the dynamic coefficient of friction and the relative velocity between the disk and a pad.

Figure 6 Simple two-degrees-of-freedom model illustrating sprag-slip behavior.

interaction of the degrees of freedom in the system. If the sliding components are oriented with respect to each other such that the normal force increases as the components slide over each other, then an unstable vibration occurs. This is because an increase in the normal force causes the disk to move laterally, which results in a sudden reduction in normal force; the normal force then increases as before due to the sliding action and the cycle repeats, leading to a sprag-slip limit cycle. For the system shown in Fig. 6, the system is stable provided that $\frac{1}{2}(\mu - \tan \theta) \sin 2\theta < c_{\text{pad}}/c_{\text{disk}}$. In a disk brake system, the contact point between the piston and the brake pad backing plate changes slightly because of wear, dirt, thermal deformation, and the

like, which may help to explain the intermittent nature of brake squeal.

Flutter Flutter is an unstable vibration that results from an interaction between modes of vibration. This type of instability is possible even when the coefficient of friction is constant. North¹⁰ was the first person to consider this mechanism as a cause of brake squeal.

The equation of motion of a brake system may be written as:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{0} \quad (1)$$

where \mathbf{M} , \mathbf{C} , and \mathbf{K} are the mass, damping, and stiffness matrices of the brake system, respectively, and $\ddot{\mathbf{x}}$, $\dot{\mathbf{x}}$, and \mathbf{x} are the acceleration, velocity, and displacement vectors, respectively. The stiffness matrix \mathbf{K} is given by

$$\mathbf{K} = \hat{\mathbf{K}} + \mathbf{K}_{\text{friction}} \quad (2)$$

where $\hat{\mathbf{K}}$ is the system stiffness matrix, and $\mathbf{K}_{\text{friction}}$ is the friction stiffness matrix that couples the normal and the tangential forces in the sliding interface and is *asymmetric*. This means that \mathbf{K} is not symmetric. The lack of symmetry in the stiffness matrix causes one or several modes of vibration to become unstable, which means that these modes have a negative damping ratio. Brake designers can currently check this out using finite element methods to model a brake system. An eigenvalue analysis of a model of a brake system can then be conducted and the real parts of the eigenvalues examined; if some of them are positive, then the system is potentially unstable at the natural frequencies associated with these eigenvalues. Ouyang¹¹ has also shown that in certain situations it is necessary to consider moving, rather than stationary, loads when conducting stability analysis.

5 METHODS TO ELIMINATE BRAKE NOISE

It is not possible for engineers to design a guaranteed noise-free brake using current knowledge and state-of-the-art techniques, although finite element analysis is frequently used to design braking systems, for example.^{12,13} Consequently, brake systems undergo extensive testing to minimize the risk that they will be noisy when installed in a vehicle. Typically, braking systems will be installed in a special test rig so that they can be tested at a variety of different speeds, different hydraulic pressures, different directions of rotation, and so forth. All of these data are recorded along with temperature and noise generated by the brake. The data is then processed and plotted on a graph similar to that shown in Fig. 7, in which the percent occurrence of noise is plotted against the noise level in decibels. The noise level, and the duration of the noise that can be tolerated by drivers, can be estimated, so that a line can be drawn on the graph separating it into two regions: acceptable and unacceptable. Provided that no data point from the test

Figure 7 Diagram showing the way in which data from a brake test would be plotted. If any data from the test is in the unacceptable region of the graph, then the brake system would fail the noise test.

is in the unacceptable region, then the brake is deemed to be acceptable from the point of view of noise.

Discussion of specific methods to eliminate brake noise follows.

Judder To eliminate judder, designers should ensure that (i) the off-brake running clearance between the disk and the pad is sufficient, by careful attention to the detailed design and tolerances, and (ii) there is careful attention paid to the thermal characteristics of the system.

Groan The approach to this problem is tackled in three ways. The first is to change the characteristics of the friction interface by changing the brake pad material. The second is to change the dynamic characteristics of the system by adjusting the modal properties of the system,¹⁴ such that the natural frequencies of the dynamic systems on either side of the sliding interface are not in close proximity. The third method is to apply damping materials to the pad, such as shims or “insulators,”¹⁵ or antiseize grease. These add viscoelastic damping to the system such that the inherent damping in the system is greater than the negative friction-induced damping and thus the brake system remains stable. It is possible, however, that in some circumstances this can make the situation worse rather than better.⁷

Squeal Brake squeal is perhaps the most annoying of all brake noise and is probably the most difficult noise problem to solve. The methods used to reduce groan are also used to reduce squeal. Additionally the disk may be smoothed using sandpaper, the pads may be chamfered at the edges and/or have slits machined in them. The center of pressure between the pistons and

the pad backing plate can also be adjusted by the use of shims. Brooks et al.¹⁶ suggest that moving the center of pressure toward the leading edge of the brake pad can have a beneficial effect, reducing the propensity of a brake to squeal. It has also been shown by Baba et al.¹⁷ that there is some benefit if the part of the disk that is attached to the wheel has variable wall thickness to disrupt the rotational symmetry.

6 SUMMARY

This chapter has described the various types of noise generated by a brake system. The fugitive nature of the problem has been highlighted, and the various mechanisms that cause brake noise have been discussed. Because of the difficulty in predicting brake noise, an experimental method used to test a brake system's propensity to generate noise has been described and the current "fixes" to brake noise problems have briefly been mentioned.

CHAPTER 93

WHEEL–RAIL INTERACTION NOISE PREDICTION AND ITS CONTROL

David J. Thompson

Institute of Sound and Vibration Research
University of Southampton
Southampton, United Kingdom

1 INTRODUCTION

Noise produced by wheel–rail interaction is a major concern in railway operations. Prediction methods for this noise using engineering models are available. A distinction must be made between (1) rolling noise, which is caused by small-scale vertical profile irregularities (roughness) of wheel and rail, (2) impact noise caused by discrete discontinuities of the profile such as wheel flats, rail joints, or welds, and (3) squeal noise occurring in curves. In each case, the noise is produced by vibrations of the wheels and track. The role of the dynamic properties of the wheel and track, along with the factors that affect sound radiation, needs to be considered. Control measures for rolling noise can be sought in reduced surface roughness, wheel shape optimization and added damping, rail support stiffness, or local shielding. The use of track-side noise barriers, which are becoming common for railways, is discussed in Chapter 58. For squeal noise, mitigation measures include friction control by lubrication or friction modifiers.

2 ROLLING NOISE

2.1 Overview of Rolling Noise

A train running on straight unjointed track produces rolling noise.¹ This is a broadband, random noise radiated by wheel and track vibration over the range of at least 100 to 5000 Hz. Its overall sound pressure level increases at a rate of roughly $30 \log_{10}(V)$ where V is the train speed.

Rolling noise is induced by small vertical profile irregularities of the wheel and rail running surfaces. This is often referred to as roughness, although the wavelength range is between about 5 and 250 mm,

which is longer than the range normally considered for microroughness. The corresponding amplitudes are much less than a micron at short wavelengths, increasing to tens of microns at longer wavelengths. Wheel and rail roughness may be considered incoherent and their spectra simply added.²

In Fig. 1 a flowchart is given of the mechanisms involved in the excitation of rolling noise. This is the basis of theoretical models.^{3–5} The roughness causes a relative displacement between the wheel and rail.⁶ Depending on their respective point mobilities, Y_w and Y_r , the wheel and rail are caused to vibrate. Local elasticity between them results in a third mobility, Y_c , corresponding to the contact spring. The vibration velocity amplitude of the wheel and rail, v_w and v_r , at frequency $\omega = 2\pi f$ due to a roughness amplitude r is given by

$$v_w = \frac{-i\omega r Y_w}{Y_r + Y_w + Y_c} \quad (1)$$

$$v_r = \frac{i\omega r Y_r}{Y_r + Y_w + Y_c} \quad (2)$$

where roughness of wavelength λ excites frequencies

$$f = V/\lambda \quad (3)$$

where V is the train speed. In practice, coupling is present in other coordinate directions as well as vertical, leading to more complex matrix equations,⁶ but the excitation remains vertical roughness. Typical vertical mobilities of the wheel, track, and contact

Figure 1 Schematic flowchart of the wheel–rail rolling noise model.

Figure 2 Typical mobilities at the wheel-rail contact in the vertical direction., wheel; —, track; — —, contact spring.

spring are shown in Fig. 2. From this it can be seen that the track has the highest mobility for frequencies between about 100 and 1000 Hz. At these frequencies the rail vibration at the contact point is approximately equal to the amplitude of the roughness; see Eq. (2).

Figure 3 shows typical predicted contributions to rolling noise of the vibrations of the wheels, rails, and sleepers (cross ties). In the present example the wheel and track have similar contributions to the overall noise, with the track contributing slightly more than the wheel.

If the roughness or train speed changes, the levels of all components in a given frequency band increase at the same rate, so that the relative importance of each component in a given band remains the same. However, as train speed increases, the relative importance of higher frequencies increases, so that the balance of wheel and track in the overall noise level changes.

2.2 Roughness and Contact Filtering

The wheel-rail contact exists over an area approximately 10 to 15 mm in length and width. These dimensions depend weakly on the wheel diameter and load.⁷ Wavelengths that are similar to, or short in comparison with this, are attenuated in their excitation of the wheel-rail system. This is expressed as a filter effect,^{8,9} as shown in Fig. 4a. Typical roughness spectra are shown in Fig. 4b. These can be seen to fall in amplitude toward shorter wavelengths (higher frequencies). To use these spectra for other speeds, the one-third octave band spectra can be simply shifted to the right or left according to Eq. (3). As speed increases and the spectrum is shifted to the right, the excitation at high frequencies increases more than that at low frequencies, leading to changes in the balance of wheel and track components of the sound radiation.

Figure 3 Typical predicted contributions in one-third octave bands from the wheel, rail, and sleepers to the wheel-rail rolling sound power level from the passage of a single wheel along the track at 100 km/h. —, total (overall A-weighted level 110.9 dB); — —, wheel (overall A-weighted level 105.2 dB);, sleepers (overall A-weighted level 96.1 dB); — · —, rail (overall A-weighted level 109.4 dB).

2.3 Wheel Modes

A railway wheel is a lightly damped resonant structure, and it is therefore instructive to consider its modes of vibration.¹⁰ Some of the modes of a wheel are shown schematically in Fig. 5. Each mode can be

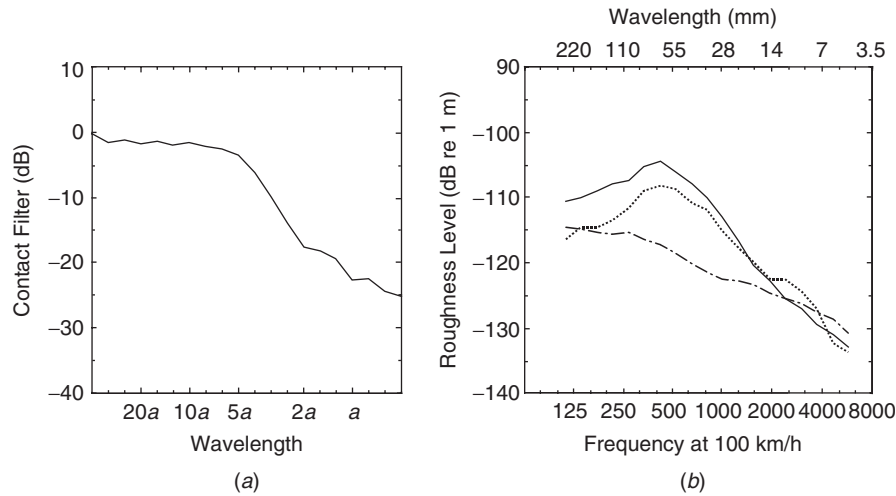

Figure 4 (a) Typical contact filter effect. The roughness wavelength is normalized to the contact patch semiaxis length, *a*. (b) Typical one-third octave wheel roughness spectra: —, disk brakes with supplementary cast-iron block brakes; — — —, cast-iron block tread brakes; — · — ·, disk brakes.

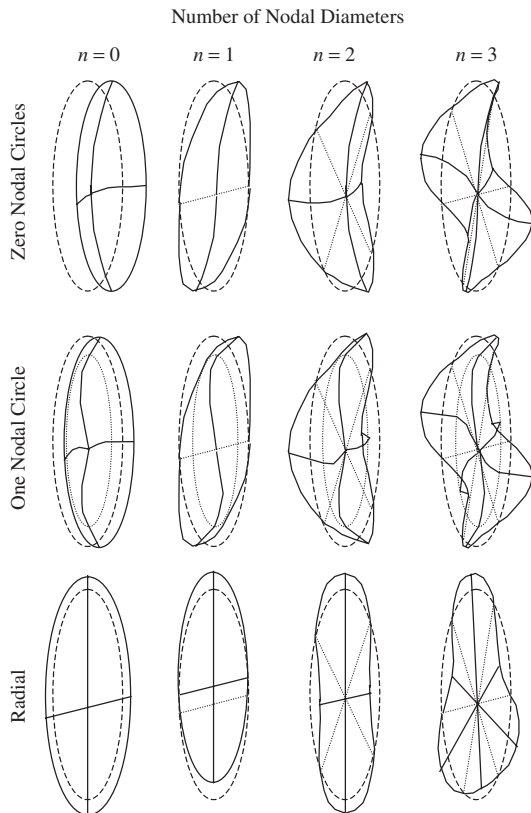

Figure 5 Schematic view of modes of vibration of a railway wheel (isometric view): —, deformed shape; — — —, undeformed shape;, node lines.

characterized by the number of nodal diameters and nodal circles. Typically, the axial modes with no nodal circles occur from around 200 Hz upward, whereas those with one nodal circle occur above about 1.5 kHz. Radial modes also occur above about 2 kHz.

Since rolling noise is excited by vertical roughness, modes with a large radial component are of greatest importance. These are the one-nodal-circle and radial modes. The one-nodal-circle modes contain significant radial motion due to coupling as a result of the asymmetry of the wheel cross section. Similarly, the radial modes contain considerable axial motion. Modes with zero or one nodal diameters experience considerable coupling with the motion of the axle and are consequently more heavily damped than modes with two or more nodal diameters.

The modes of importance in rolling noise, the radial and one-nodal-circle modes with two or more nodal diameters, usually occur at frequencies above 1.5 kHz and correspond to the part of the frequency range in which the wheel component of noise is greatest, as seen in Fig. 3. They can be seen as the sharp peaks in the point mobility shown in Fig. 2.

2.4 Track Vibration and Decay Rates

A railway track is effectively an infinite waveguide, and therefore its vibration is characterized not by natural modes but by propagating waves.^{11,12} The frequency response of the track is seen from Fig. 2 to be much flatter than that of the wheel. At low frequencies, the support structure, consisting of ballast, sleepers, and usually a resilient rail pad beneath the rail, prevents the propagation of waves. In this frequency region the sleepers are strongly coupled to the rails. Above a few hundred hertz, free waves propagate in the rails as bending or torsional waves.

Above about 1 kHz, cross-sectional deformation of the rail occurs and additional wave types occur as a result.

The periodic, or quasi-periodic, support of the rails at the sleepers is only significant at frequencies where the rail half-wavelengths are an integer fraction of the sleeper spacing, the so-called pinned-pinned frequencies. Here standing-wave patterns are formed with nodes at the sleepers. The most important such frequency is at about 1 kHz in the vertical direction for a sleeper spacing of 0.6 m. These are not included in the curve in Fig. 2, which represents a continuously supported rail. Their influence is greater for stiff pads than for soft pads and is much smaller for lateral vibration than for the vertical direction. The pinned-pinned behavior does not have a large influence on the noise radiation except through its effect on roughness growth.

The rail vibration determined by Eq. (1) corresponds to the contact point. As waves are transmitted along the rail, a large section of rail can vibrate due to the excitation of each wheel. This is limited by the damping of the track, measured in terms of the decay rate with distance, as discussed further in Section 3.5.

2.5 Sound Radiation

The sound radiation from the wheel and rail can be determined in terms of sound power W simply by using the standard expression

$$W = \rho c S \sigma \langle v^2 \rangle \quad (4)$$

where ρc is the acoustic impedance of air, S is the surface area of the radiating body (both sides), and $\langle v^2 \rangle$ is the spatially averaged mean-square normal velocity. For the rail W represents the power per unit length and S the perimeter length. The parameter σ is the radiation efficiency (or ratio) and can be evaluated by analytical or numerical models. At high frequency $\sigma \rightarrow 1$, whereas at low frequency it is considerably less than 1 depending on the dimensions of the wheel

or rail and the mode shape. Figure 6 shows radiation efficiencies of a wheel in various modes of vibration¹³ and of a rail vibrating vertically or laterally.¹⁴ This infinite (two-dimensional) model of rail radiation gives good results at frequencies above about 250 Hz, but at low frequencies the decay of vibration along the length of the rail is quite rapid and the source becomes more like a point source. Corrections to the calculation using the two-dimensional model can be applied for this.¹⁴ The directivity of sound radiation from wheels and rails is not particularly strong and can be approximated by simple monopole or dipole directivities, particularly if only the average sound pressure during the passage of a train is required.

2.6 Measurement Methods for Railway Noise

The international measurement standard for exterior noise from trains¹⁵ has long been considered to provide inadequate control of the measurement situation. It prescribes a measurement position at 25 m from the track and 3.5 m above rail head level. Its greatest inadequacy lies in the potentially quite large variability that can arise due to the surface roughness of wheel and rail, and to a lesser extent the variability due to track construction. This standard is being revised to include a specification of a rail roughness limit. If the rail roughness is below this limiting spectrum, it is anticipated that the results should be relatively insensitive to the actual rail roughness (although they will not be completely unaffected by it) due to the presence of the wheel roughness, which is generally greater than the rail roughness limit.

In parallel, efforts have been made to develop measurement standards in connection with the introduction of vehicle noise emission limits as part of the European Community Technical Specifications for Interoperability.¹⁶ These differ in the details of the roughness limit and the specifications for the track at the test site.

For the measurement of rail and wheel roughness, several different measurement systems have been

Figure 6 Radiation efficiencies (ratios) (a) of a wheel in axial modes with 0 nodal circles (number of nodal diameters indicated), (b) of an infinite rail vibrating vertically (—) or laterally (---), calculated using boundary element models.

developed.^{17,18} Various comparisons have been made between the results measured by different systems,^{2,19} but the case remains that the results obtained depend on the measurement system used and the way in which the data are analyzed, so that great care is needed.

3 REDUCING ROLLING NOISE

3.1 Introduction

According to the flowchart in Fig. 1, reductions of rolling noise can be sought by reducing the input (the combined surface roughness), modifying the response and radiation of the wheels and track, or by introducing shielding to reduce sound transmission.²⁰ If the combined roughness is reduced, the whole noise output is reduced in proportion; for other changes the overall reduction depends on the relative importance of the wheel and track and on any interaction between them. Moreover, combinations of measures are not wholly additive in their effect.

3.2 Reducing Roughness

Vehicles that are braked by cast-iron blocks acting on the wheel tread are common in Europe. These develop a corrugation pattern on the wheel running surface that yields higher rolling noise levels. Replacement by disk-braked stock can yield reductions of typically 10 dB,²¹ and, as most modern passenger stock is disk-braked, this has led to considerable reductions in noise over the last two decades. Alternative, for example, composite, brake block materials can also be used in the tread brake system to similar effect. Indeed, North American freight stock is usually tread-braked using composite blocks. However, other problems such as wheel heating have to be overcome before these can be introduced on a like-for-like basis.

Rail roughness develops at some locations into a near periodic corrugation. Considerable understanding of the mechanism of its development has been produced in recent years,²² involving track dynamic behavior as well as metallurgy. Strong antiresonances of the track system such as the pinned-pinned mode can induce high dynamic forces enhancing corrugation formation. Nevertheless the case remains that the usual remedy is grinding of the rail head using special grinding trains. The use of such grinding trains has other advantages in terms of maintaining rail transverse profiles and removing cracks and other surface damage before they develop into rail failures.

3.3 Wheel Damping and Shape

It might appear that the light damping of a wheel (see Fig. 2) makes it an ideal candidate for added damping treatment. However, the coupling with the track introduces considerable effective damping that must be exceeded if a damping treatment is to be effective against rolling noise. Thus, although the wheel itself has damping loss factors around 10^{-4} to 10^{-3} , the effective loss factor increases to around 10^{-3} to 10^{-2} when coupled to the rail.¹⁰

Additional wheel damping can be provided by constrained layer treatments or tuned absorber

systems.^{23,24} In some situations overall reductions of over 6 dB have been obtained,²⁵ but in such situations the starting point is clearly one in which the wheel dominates in the sound radiation. Where the track is the dominant source initially, the overall reductions will be limited to only 1 or 2 dB unless simultaneous noise reduction of the track is applied.

It is also possible to reduce the wheel component of noise by optimizing its shape. A symmetrical web cross-sectional design is around 2 to 3 dB quieter than a curved web cross section due to reduction of the coupling between radial and axial motion. A thicker web is also beneficial, due to the increase in modal frequencies. This means that less modes are excited in the frequency range below the cutoff of the contact filter. Similarly, a reduction in diameter increases the modal frequencies while also reducing the radiating area. In one study, a combination of these features (with an 18% reduction in diameter) led to predicted reductions in wheel noise of over 10 dB.²⁶ Very small wheels are used in some specialist low-floor freight wagons and have been found to have wheel components of noise of up to 20 dB less than more usual standard designs. However, the smaller diameter leads to a slightly shorter contact patch, and consequently to a lessening of the contact patch filter effect and a small increase in noise from the rail.²⁷

Resilient wheels can also lead to a reduction in the noise from the wheel, due to isolation of the wheel tread from the remainder of the wheel, and increased damping, but this too can lead to an increase in noise from the rail.²⁸

3.4 Rail Pad Stiffness and Rail Damping

The stiffness of the pad inserted between the rail and the sleepers has a moderate effect on the input mobility of the rail but a much greater effect on the decay of rail vibration with distance and the coupling between the rails and sleepers.²⁹ The effect is summarized in Fig. 7. This shows that as the pad stiffness is reduced, the rail becomes progressively decoupled from the sleepers, leading to reduced sleeper noise, but the rail vibrates over a greater distance due to its reduced decay rate, giving greater rail noise. The wheel noise is virtually independent of these changes. An optimum can be envisaged where the overall noise has a minimum. However, this corresponds to a rather stiff pad. In fact the modern trend in track design is toward the use of softer pads to minimize track component damage due to high impact loads and also to reduce the likelihood of rail corrugation. Therefore, there is a need to increase the track decay rates without increasing the rail pad stiffness.

The results of Fig. 7 do not take account of the nonlinear stiffening of the rail pads under train loads, particularly prevalent for softer pads, which tends to reduce the slope of the dependence of noise on pad stiffness.³⁰ Rail pad properties also change over time.

In an attempt to increase the rail decay rates, several rail damper systems have been developed in recent years.^{31,32} The most successful of these depend on

Figure 7 Predicted dependence of rolling noise on rail pad stiffness: —, total track noise; — — —, rail vertical;, rail lateral; + + +, sleepers; — x —, wheel.

using a damped mass-spring system added to the rail. The maximum damping effect is produced at the tuning frequency of the system, but due to the use of high damping materials, considerable damping is achieved over a broad frequency range.

An example of the effect of using such dampers is given in Fig. 8.³² Here the noise from the track has been reduced by about 6 dB. The actual reduction achievable depends on the pad stiffness—for tracks with stiff pads the reductions are unlikely to exceed 2 to 3 dB.

Figure 8 Measured effect of applying silent track rail dampers on one-third octave band sound pressure spectrum at 3.7 m from the track, train speed 100 km/h, low noise wheels: —, with absorbers (overall A-weighted level 85.1 dB); — — —, reference track (overall A-weighted level 90.5 dB).

3.5 Local Shielding

As an alternative to the various structural measures mentioned above, or to complement them, it is possible to use a combination of low barriers close to the rail and vehicle-mounted shields. The success of such a system relies on ensuring that any gap through which direct sound can be radiated is minimized. Effective experimental configurations have been shown to demonstrate reductions of 10 dB.³³ In other cases, where the loading gauge and track structure gauge requirements prevented the barrier and shields from overlapping one another, reductions of less than 3 dB have been found.³⁴

4 IMPACT NOISE

Impact noise is generated when the wheel rolls over a discrete discontinuity in the rail surface, for instance, at rail joints, welds, or points and crossings.³⁵ Additionally, discontinuities can occur on the wheel surface, for example, “wheel flats” due to sliding of the wheel during braking in imperfect adhesion conditions.

Noise is generated by a similar mechanism to that applying for rolling noise, a vertical relative displacement input between the wheel and rail. The relative contributions of wheel and track vibration to the noise radiation follow the same pattern as for rolling noise. However, since large discrete inputs are involved, the nonlinearity of the contact spring becomes important and in extreme cases the wheel-rail contact force can become zero.^{36,37} Very large dynamic forces occur on reestablishment of contact (impact).

Although the same mitigation measures can be used as for rolling noise, the most effective is adequate maintenance. Good wheel slide protection can prevent the formation of wheel flats. Monitoring systems can be used to detect wheel flats and to recall those vehicles for wheel reprofiling provided they are properly installed. Similarly, good maintenance of rail joints and straightening of rail welds is important for minimizing impact noise. The use of swing nose crossings can eliminate gaps at high-speed crossings to reduce impacts and hence noise.

5 WHEEL SQUEAL

5.1 Mechanisms

When a railway vehicle traverses a sharp curve, the front axle of each bogie (truck) tends to run in flange contact on the outer rail and with a significant angle of attack, see Fig. 9a. The rear wheelset runs in flange contact at the inner rail at low speed, but its angle of attack is much less than the leading axle.

As a result of the large angle of attack at the leading wheelset, the leading inner wheel experiences a considerable lateral sliding velocity in addition to the forward velocity of the vehicle; that is, in order to traverse the curve it must slide sideways as well as roll forward. This induces a frictional (or creep) force. In common with many dry friction phenomena (see also Chapter 92), this leads to dynamic instability since at large sliding velocities the frictional force falls with

Figure 9 Excitation of squeal noise (a) attitude of typical two-axle bogie in a sharp curve showing forces acting on each wheel and (b) typical rolling friction characteristic.

increasing sliding velocity; see Fig. 9b. This can be seen as introducing a negative damping to the system. At large amplitudes the motion becomes a stick-slip type of oscillation. The vibration usually corresponds to one of the modes of vibration of the wheel, and a squealing noise is produced with a strongly tonal character.

The wheel modes of relevance to squeal noise are those with a large lateral component at the wheel-rail contact point and a small radial component. Thus the zero-nodal-circle modes (see Fig. 5) are usually excited in curve squeal. Although the rail also vibrates at the squeal frequency, the noise radiation is dominated by the wheel.

Models for squeal noise due to the above mechanism have been developed by Rudd,³⁸ Fingberg,³⁹ Heckl,⁴⁰ and de Beer.⁴¹ In addition to the above mechanism, squeal noise is also generated at the flange contact with the outer rail.⁴² This generally produces a higher frequency, more intermittent noise, often in the frequency region above 5 kHz, although it can also occur at lower frequencies. Other forms of curving noise occur, for example, due to low-frequency stick-slip in the longitudinal direction involving torsional modes of the wheelset. Names such as "graunching" and "judder" describe some of these lower frequency phenomena. Further research is needed into these various phenomena. The discussion in the following section is limited to the squeal noise generated by lateral slip at the rail head.

5.2 Reduction of Curve Squeal

Since squeal noise involves a dynamic instability, the addition of a small amount of damping to the wheel can often eliminate the excitation and produce noise reductions of tens of decibels. As well as the damping systems described in Section 3.3, ring dampers have been found to be effective.^{43,44} Resilient wheels also increase the damping sufficiently to reduce the instance of squeal noise.⁴⁵

Rail damping has also been applied and found to reduce curve squeal, although it is not clear according to the mechanism described above how this is achieved. Such a measure is attractive as it only needs to be applied at the locations where problems occur.

Other solutions are based on modifying the friction behavior. Squeal noise is less prevalent in wet weather and so water sprays have been used effectively. Lubrication using grease is also commonly used, although this is normally only applied to the gauge face of the rail, not to the running surface where it would compromise braking performance. This, therefore, does not modify directly the friction behavior at the leading inner wheel. Instead, it modifies the attitude of the bogie in the curve.

Friction modifiers have been introduced in recent years that can also be applied to the rail head.⁴⁶ Rather than reduce the overall friction level, these aim to reduce the "negative friction" characteristics, introducing instead a positive slope of the friction curve and eliminating the instability.

6 CONCLUSION

Theoretical models for rolling noise are well developed and can be used to design intrinsically quieter wheels and tracks. Models for impact noise and curve squeal are also quite well developed, although many aspects remain to be solved. Further information about reducing rolling noise, in particular, and railway noise, in general, can be found in chapters of various books.^{47–50}

INTERIOR TRANSPORTATION NOISE AND VIBRATION SOURCES - PREDICTION AND CONTROL

CHAPTER 94

INTRODUCTION TO INTERIOR TRANSPORTATION NOISE AND VIBRATION SOURCES

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

Noise and vibration are important considerations for the comfort of operators and passengers in surface transportation vehicles, off-road vehicles, aircraft, and ships. Noise and vibration energy is transmitted from the sources to the passenger, operator and crew by airborne and structure-borne paths. The amount of noise and vibration energy reaching people depends upon the strength of the individual sources and the effectiveness of structural paths. The strength of the individual sources and of the paths varies from vehicle to vehicle and depends on vehicle operating conditions including power plant settings, speed, and also upon the frequency range considered. For many types of vehicles, aircraft, and ships, the dominant path for low-frequency noise (below about 400 to 500 Hz) is structure borne. In most cases, in the mid- to high-frequency range, airborne paths from the noise sources to occupied spaces tend to dominate. The relationship between airborne and structure-borne paths also varies from vehicle to vehicle and is somewhat different for aircraft and ships, since the flow noise caused by the turbulent boundary layer fluctuations is a more important source of excitation than with the other vehicle types. Interior noise level criteria depend upon the vehicle type and the occupied space considered. For passengers, speech communication and privacy are the main concerns, while for truck, railroad vehicle, and ship engine room operators and crew, hearing protection and speech communication remain as important issues.

2 INTERIOR ROAD VEHICLE NOISE AND VIBRATION

The interior noise in the occupied spaces of automobiles, buses, and trucks is mainly caused by the engine, exhaust, transmission, power train, tire/road interaction, and wind/structure interaction. Many of the same noise and vibration problems exist in rail, off-road vehicles, and passenger ships as in surface transportation vehicles. Airborne and structure-borne paths from noise and vibration sources are also of concern with these other vehicles and means of transportation. Some of the discussion in Section 2 of this chapter is also relevant to these other types of vehicle. With automobiles, trucks, and buses, structure-borne

noise usually tends to be dominant below about 400 to 500 Hz, while airborne noise from tire/road interaction and airflow/structure interaction (wind noise) tends to dominate in the mid- and high-frequency ranges.

Chapter 95 describes the relative contributions from different noise and vibration sources and paths to the vehicle interior. Interior noise levels depend also upon vehicle operating conditions and in particular on speed. During acceleration, engine noise tends to dominate; while during cruise conditions, above about 80 km/h, tire noise becomes the major contributor, and at higher speeds above about 120 km/h, wind noise becomes dominant. Improper sealing around vehicle doors, windows, dashboards, windshields, and the like causes excessive external turbulent pressure fluctuations from airflow over the vehicle (wind noise) to be transmitted to the vehicle interior. This is known as aspiration, as discussed in Chapter 95. Some luxury vehicles have multiple door seals to accomplish effective sealing to reduce the transmission of these external turbulent pressure fluctuations to the occupied interior.

To reduce airborne and structure-borne noise reaching the vehicle's occupants, various well-known techniques are often used, including (1) increasing structural damping, (2) improving the transmission loss of body panels and windows, (3) increasing the use of sound-absorbing materials in the engine, passenger, and luggage compartments, and (4) vibration isolation of mechanical components. Hirabayashi et al. have described how all four of these techniques are used in the automotive industry to reduce noise and vibration in vehicles.¹ Rao has provided a useful review of the use of vibration damping materials in automobiles and commercial aircraft.² Polce et al. have also presented a detailed study on improvements in cabin noise obtained by using damping treatments.³ Add-on constrained layer, spray-on, and integral damping materials are often used. Table 1 lists various locations on a typical automobile, such as illustrated in Fig. 1, where these are often used.

Damping materials are generally more effective at reducing structure-borne vibration (particularly panel resonances) rather than at reducing the airborne sound transmitted through panels. Of the damping approaches, spray-on damping material is easiest to

Table 1 Automotive Applications¹

apply, but constrained damping layers comprised of a viscoelastic layer constrained by a thin surface layer normally provide higher damping for the same weight or less weight through shearing action in the viscoelastic layer. The oil pan (or sump) of an engine can be responsible for radiating 50% of the sound power of an engine.^{2,4} Figure 2 shows the A-weighted interior sound pressure level in a vehicle at the driver's ear position with: (a) a regular galvanized steel oil pan and (b) with the oil pan replaced by a high damping laminated steel oil pan.² The A-weighted sound pressure levels were obtained during a stationary

**Figure 2** A-weighted sound pressure levels obtained during a stationary engine runup tests for two different oil pans with increasing engine rpm.²

engine run up test with increasing engine revolutions per minute (rpm). Figure 2 shows that reductions in the A-weighted interior noise level of about 5 dB were obtained with the laminated steel oil pan.

Water-based spray-on damping materials are also used in automobile manufacture. Their advantage is that they can be sprayed robotically on areas such as floor panels and other locations that are hard to reach (such as wheel housings).² Thicknesses of between 1 and 3 mm are normally used. The disadvantage of the use of such materials is that they require costly spray and robotic equipment.² It is believed that the use of body and floor panel damping is effective mostly at reducing structure-borne interior automobile noise in the 100- to 500-Hz range. Although increased damping normally has disappointing results in increasing sound insulation, spray-on damping materials do also add *mass*, which can also reduce airborne sound transmission through areas such as floor panels.

The use of laminated glass to reduce automobile interior noise continues to increase.⁵ Figure 7 in Chapter 95 shows the effect of using laminated glass in reducing wind noise and tire/road noise. The reduction in airborne noise by the use of the laminated glass is probably caused by the material impedance mismatch, which results in sound reflection at each interface layer; while the reduction in structure-borne noise is likely caused mostly by the increase in vibration damping produced by use of the laminated glass. At some frequencies the damping loss factor for the laminated glass is twice that of the standard tempered glass. The increased damping can reduce sound transmission in the coincidence frequency region.

The use of laminated vibration-damped steel (LVDS) is now being studied for its capability in reducing airborne and structure-borne noise reaching the passenger compartment from the engine and power train components. See an example of an LVDS dash panel in Fig. 3. The advantage of LVDS is that no add-on damping treatment is needed. Improvements in sound quality and speech interference level through the use of LVDS must be considered in light of cost and other factors.

In the automotive industry, materials used to enclose a noise source (such as the engine) or the passengers (the cabin enclosure) are usually termed *barrier* materials. Such barrier materials are required

Figure 3 Dashboard panel made of laminated vibration damped steel.²

to reduce airborne sound reaching the cabin from noise sources, including the engine, fan, exhaust system, tires, and wind. Below the coincidence frequency region, the sound transmission loss (TL) of such materials is mostly dominated by the mass/unit area (m) of a partition (see Chapters 54 and 56). For single-layer partitions this means that TL increases by 6 dB for each doubling of frequency or by 6 dB at a given frequency if m is doubled. Multilayer partitions, particularly with intervening air gaps between layers, can achieve TL results quite a lot better than mass law would predict, and the TL for such panels can be more like 12 dB/octave rather than 6 dB/octave. Great care must be taken to avoid air leaks for high

values of TL to be achieved in practice. Figure 4 shows locations where barrier materials are often applied in an automobile.

Once airborne and structure-borne sound has penetrated into the cabin, the sound can be absorbed effectively by the use of sound-absorbing material. See Chapters 54 and 57. Generally, thicker sound-absorbing materials are better than thinner ones, and a material works best if its thickness approaches one-quarter wavelength of the sound. This thickness can only be approached at quite high frequency in an automobile. Figure 5 shows locations where sound-absorbing materials are often applied.

A variety of theoretical methods, such as statistical energy analysis, finite element analysis, boundary element analysis, and computer-aided engineering methods are used to predict sound and vibration energy transmission from exterior sources to the vehicle interior as described in many publications.⁶⁻³¹ Because of complicated structural geometries, analytical approaches must often be supplemented with laboratory noise testing in anechoic rooms, wind tunnels, and actual tests with real full-scale vehicles on dedicated test tracks. Chapter 95 discusses noise sources and paths, methods of modeling, and noise reduction approaches in more detail. With automobiles and trucks, it is insufficient to simply reduce noise reaching the passenger compartment. Passengers expect different types of vehicles such as passenger cars, sports

Figure 4 Typical locations in an automobile where “barrier” materials are utilized.

Figure 5 Typical locations in an automobile where sound-absorbing materials are utilized.

cars, sport utility vehicles, luxury cars, and light trucks to have distinctive sounds. In some cases, manufacturers' brand names are often associated with a particular vehicle sound, and it is important not just to reduce interior noise but also to consider the quality of the sound. See Chapter 67 for more detailed discussion on sound quality.

3 NOISE OF RAILROAD CAR AND RAPID TRANSIT SYSTEM VEHICLES

The main concern in the design of railroad passenger cars and rapid transit system (RTS) vehicles is the provision of a comfortable noise environment for the passengers. A balance must be achieved between acoustical privacy and speech interference. Passengers want the sound pressure level to be low enough so that they can carry on conversations and use cell (mobile) telephones easily. On the other hand, they do not want the level to be so low that their conversations can be overheard by other passengers nearby. The noise environment in railroad car and RTS vehicles is caused by a variety of sources that depend mostly upon the power plant setting and vehicle speed. At low speed, interior noise is caused mainly by the power plant and air-conditioning systems. Wind noise is normally unimportant for slow or medium-speed RTS vehicles, but it can become the dominant noise source with railroad systems when they are operated at very high speeds. The balance between acoustical privacy and speech interference changes with speed and it is difficult to optimize this balance without the use of artificial masking noise during low speed or stationary operations of the vehicles. Various power plants are used to propel the railroad and RTS vehicles, and in some high-speed railroad vehicle designs several sets of traction motors are used to drive each passenger car, instead of just the locomotive, or individual electric motors are employed to drive the vehicle wheels directly. Wheel-rail noise becomes important at medium and high speeds and depends upon rail roughness and wheel wear.³²⁻³⁴

Soft rubber wheel suspensions have been used on some rapid transit systems (e.g., Mexico City) in an attempt to reduce noise. Rubber or elastomeric damping blocks have also been built into the wheel systems of some other passenger railcars and crew locomotives.³⁵ If damping blocks and damping rims are implemented, they should be properly tested to demonstrate that they can be used safely in service.

Figure 6 shows the A-weighted interior noise level at moderate speeds for one particular railcar.³⁵ It is observed that the A-weighted sound pressure level increases at a rate of 9 to 10 dB for each doubling of speed in the range of measurements shown. Subjectively, this amounts to approximately a doubling of linear loudness (in sones) for a doubling of train speed. It should be emphasized, however, that this result may be somewhat different for other railcar designs.

Figure 7 shows acceleration levels measured on the railcar floor with conventional solid wheels and

Figure 6 Sound pressure level as a function of train speed.³⁵

Figure 7 Comparison of floor vibrations for solid wheel and low-noise wheel.³⁵

Figure 8 Comparison of interior noises for solid wheel and low-noise wheel.³⁵

low-noise wheels. Figure 8 shows a comparison of the interior A-weighted sound pressure level of the same railcar as in Fig. 6 with conventional wheels and with the low noise wheels. Figure 8 demonstrates that in this particular railcar, at the speeds shown, the wheel/rail interaction noise is very important. This study shows that there is not complete correspondence between the reduction in the floor acceleration level and the reduction in interior sound pressure level, achieved by the use of low noise wheels. This indicates

the presence of other noise sources, such as power plant, wind noise, and air-conditioning noise.

As is described in Chapter 96, it is normal practice to set target noise level goals for passenger comfort and to specify maximum power plant and air-conditioning system source sound powers from equipment manufacturers and suppliers in order to achieve the noise targets. Target A-weighted equivalent interior sound pressure levels of between 65 and 70 dB are commonly chosen. To achieve such target noise levels, the vehicle structure must also be carefully designed from the start so that the noise and vibration paths sufficiently attenuate the power plant, wheel/rail, wind, and air-conditioning noise reaching the passenger compartments. The contribution to the internal noise caused by wheel/rail interaction can be predicted from knowledge of the roughness of the rails. It is important for the rail roughness levels to be defined at the beginning of the acoustical design process. Both airborne and structure-borne paths must be considered. Cabin wall airborne sound transmission properties, structural damping, and interior sound absorption all affect the transmission of sound and vibration and the resulting sound pressure level in the cabin interior. Accurate prediction of the interior cabin noise can only be made with a knowledge of all of the external and internal cabin noise and vibration sources and paths.

Chapter 96 discusses noise sources and noise level targets in high-speed railroad cars. Chapter 97 describes target noise levels in rapid transit system cars and the acoustical design processes commonly used to achieve them. There is extensive literature on noise and vibration sources and paths in rail vehicles.^{36–44} Squeal noise is a problem experienced on curved tracks.^{39,42}

4 INTERIOR NOISE AND VIBRATION OF OFF-ROAD VEHICLES

Off-road vehicles are used for a variety of tasks including earth moving, road, railway and airport construction, and use on building sites and in agriculture, as described in Chapter 98. The vehicles are provided either with wheels or tracks for propulsion. Cabs are used to protect the operator from rollover and other operational hazards, from the weather, and from noise and vibration. One of the main concerns with these vehicles is to provide a safe acoustical environment for the operator inside the cab. To achieve this, the time-averaged A-weighted equivalent sound pressure level inside the operator cab should be no higher than about 75 dB. Since noise levels vary with time as vehicles undertake various activities such as earth moving or grading, noise measurement methods to record the sound pressure levels generated have been standardized internationally, which take account of this operational variability. A-weighted internal cab noise measurements are normally made with a single microphone in the presence of the operator. The microphone is oriented horizontally at the operator head height and pointed forward or in the direction in which the operator normally looks.

Interior noise levels depend upon the strength of the noise and vibration sources and paths including the power plant, exhaust, transmission, hydraulic systems, mounting systems, and wheel and/or track ground surface interactions. It is important to ensure that the sources are vibration isolated from the vehicle structure and that proper care is taken to achieve satisfactory operator sound isolation by providing a suitable transmission loss (sound reduction index) for the cab enclosure. Air leaks should be minimized if the cab noise level can only be achieved with windows closed. Structural damping and interior sound-absorbing material, if properly used in the design stage, can help achieve the necessary interior cab noise level design goals.

Analytical models, which are often employed in the design of off-road vehicle cabs, include statistical energy analysis, finite element analysis (FEA) and boundary element methods (BEM).^{46,47} The track undercarriage can become a dominant noise source for tracked vehicles. Experimental confirmation that cabin noise goals have been achieved is necessary during prototype vehicle development and testing. The sound pressure level depends on vehicle operations including earth moving and other working cycles. Chapter 98 discusses the interior noise and vibration of off-road vehicles and methods to reduce the interior noise.

A-weighted sound pressure levels in off-road vehicle cabs have been measured to be as high as 107 dB. See Ref. 48. By proper passive noise control approaches, these levels can be reduced considerably as described in Chapter 98. Approaches vary from mostly experimental to almost completely theoretical.^{45–47} Both structure-borne and airborne noise and vibration paths to the cab interior must be considered.⁴⁶ A quite sophisticated study of the noise transmitted into the operator cab of an agricultural machine using both scale models and theoretical FEA and BEM has been reported.⁴⁶ Figure 9 shows the operator cabin studied by Desmet et al. The scale model was used to obtain experimental results. Both FEA and BEM meshes were used for the cabin structure and acoustical space. A comparison between the measured and predicted sound insertion loss (IL) of the model cabin is shown in Fig. 10.

5 AIRCRAFT CABIN PASSIVE NOISE AND VIBRATION CONTROL

As discussed in Chapter 99, low interior cabin noise is important for passenger and crew comfort. High cabin noise levels experienced in passenger jet aircraft in the 1960s and 1970s have now been considerably reduced by the use of turbofan engines instead of noisy pure jet engines. Obtaining satisfactory cabin noise environments, which satisfy both speech interference and speech privacy criteria, remains a difficult problem since there is a large variety of noise sources that become dominant during different aircraft operating conditions. As is the case with surface transportation vehicles, with aircraft there are many different noise sources that contribute to the acoustical environment inside aircraft cabins.

Figure 9 Operator cabin of an agricultural harvester machine.⁴⁶

Figure 10 Measured and predicted agricultural cabin sound insertion loss.⁴⁶

The dominant cabin noise sources are mainly those exterior to the aircraft cabin and include power plant noise and vibration and turbulent boundary layer excitation. The relative strength of the sources depends upon the aircraft operating conditions and flight speed. Internal cabin noise sources include air-conditioning systems, hydraulic systems, and electrical and mechanical equipment. These sources are mainly of concern with aircraft during ground operations

before takeoff. Power plant noise tends to be dominant at low flight speeds during takeoff and landing, while the noise generated by turbulent boundary layer excitation of the cabin walls is dominant at higher speeds, after takeoff and during subsequent climb, during landing descent, and in cruise conditions.

In the front of the cabin, turbulent boundary layer noise tends to peak at high frequency. While, in the middle to rear of the cabin, the boundary layer noise peaks at a much lower frequency. This is because the turbulent eddies in the thick boundary layer at the rear of the aircraft are larger than those in the thinner boundary layer at the front of the cabin. Jet noise is likewise more pronounced at the rear of the aircraft cabin for wing-mounted engines since jet noise is predominantly radiated downstream. See Chapters 83 and 89. For passenger aircraft with rear-mounted jet engines, the engine noise is mainly experienced at the rear part of the cabin. In cruise conditions, the noise from the engines is mostly structure borne and is caused by small out-of-balance forces created by minor aircraft engine manufacturing imperfections.

To reduce interior cabin noise caused by engine noise and boundary layer noise, it has been normal practice to make use of lightweight damping materials. In the case of propeller aircraft, passive dampers are sometimes used, which are tuned to the blade passing frequency and/or the second and third multiples and that are attached to the fuselage interior skin panels.

In the case of jet passenger aircraft, constrained layer dampers are normally used and are placed at the center of skin pockets between the stringers and ring frames. Figure 11 shows a typical “stacked” damper system, and Fig. 12 shows the skin pockets of a passenger jet aircraft where they are usually located. In most designs, a layer of viscoelastic damping material is constrained by a thin metal constraining layer of metal or Kevlar. A spacer is located between the base structure (airplane fuselage skin) to move the viscoelastic damping material as far as possible away from the neutral axis of the fuselage skin. The spacer is normally slotted to reduce its weight and minimize its bending stiffness. Ideally, the spacer should also have high shear stiffness. By this means, the shear distortion in the viscoelastic damping layer is magnified as the aircraft skin flexes in bending, and the damping effectiveness of the stacked damper is increased. Since the aircraft fuselage skin gets very cold at cruising altitude and the stacked damper is in close contact with the aircraft skin, special viscoelastic

Figure 11 Stacked constrained layer damper system.²

Figure 12 Interior of fuselage skin showing pockets between the stringers and ring frames.²

Figure 13 Use of constrained layer damping with an aircraft stringer.²

material must be used that has a maximum damping loss factor at the skin temperature during normal cruise conditions.

Viscous constrained damping layers are often used on aircraft stringers. Figure 12 shows the location of stringers on an aircraft fuselage skin. Figure 13 shows how the damping material is constrained between an aircraft stringer and the fuselage skin, which in this case acts as the constraining layer. Damping layers are also often applied to ring frames. Since the ring frames are in contact with the cabin air, they are not as cold as the fuselage skin and the viscoelastic material used is normally selected to have a maximum damping loss factor closer to the normal cabin air temperature.

In some parts of the aircraft cabin, separated flow and shock waves can occur near abrupt changes in

the airplane geometry. For example, such geometric changes usually occur near the cockpit and can cause intense noise to be experienced nearby in the cabin. Cabin noise in propeller-driven aircraft poses a special problem, which is somewhat different from the interior noise of passenger jet aircraft. The interior noise from the power plants of propeller-driven aircraft is dominant over the entire flight regime, not just during takeoff and landing. Propeller noise occurs at the fundamental blade passage frequency and the first few integer multiples, and for wing-mounted engines this noise can be intense if the propellers pass close to the passenger cabin fuselage. The propeller noise, being predominantly low frequency, is difficult to control using passive methods. There is obviously a limit to the amount of mass, which can be added to reduce airborne sound transmission. Sound-absorbing materials are not very effective either at low frequency. The cabin noise levels can be reduced to some extent by the use of damping materials, which will also improve speech intelligibility. However, vibration transmitted from the engines to the airframe and thus resulting in cabin noise is also a matter of concern.^{49,50}

6 ACTIVE CONTROL OF AIRCRAFT CABIN NOISE AND VIBRATION

Although passive noise source and path control methods have been improved considerably in recent years, in some cases aircraft cabin noise environments are still unsatisfactory. This is particularly true in the case of propeller-powered aircraft, and active control methods have been successfully employed to reduce the low-frequency cabin noise at the fundamental blade passing frequency and the first few multiples.

Active noise control systems are particularly successful in the low-frequency region in which the cabin sidewall sound transmission loss is poor and at which the blade passing frequency occurs. The active control is achieved by introducing multiple secondary sources in the cabin and the use of active headsets or "silent" seats. In the case of silent seats, small secondary sources are located in the top of the passenger seats in order to create a zone of "silence" near to the passenger's head. Structure-borne noise is also reduced on some aircraft by locating active 180° out-of-phase vibration sources near to aircraft engine mounts. Attenuation of broadband cabin noise is a more difficult task but can be undertaken provided sufficient numbers of secondary 180° out-of-phase noise sources are located inside the cabin. Since jet power plant noise has been successfully reduced in recent years, and in any case is minimal during cruise conditions, broadband turbulent boundary layer noise is becoming recognized as an increasing problem during cruise conditions. Active noise control of aircraft cabins is discussed in Chapter 100. Active control of the structure close to the engine can also be undertaken to reduce structure-borne noise reaching the passenger cabin.⁵¹ See Chapter 64 for further discussion on active vibration control, and Chapter 63 for further discussion on active noise control.

Figure 14 Percentage of passengers choosing various criteria needing improvement on a cruise ship.⁵²

7 CONTROL OF SHIPBOARD CABIN NOISE AND VIBRATION

Many of the same noise problems exist in passenger ships as in surface transportation vehicles and aircraft. Airborne and structure-borne paths from noise and vibration sources can be of similar and sometimes of equal concern during different ship operations. The main sources include the power plant machinery and the propulsion units including screws and propellers.

Noise levels can be intense in the engine room compartments of ships, and consideration needs to be given to providing low enough sound pressure levels so that speech communication is possible and audible alarm signals can be heard. Crew comfort must also be considered in crew rest areas so that they can recuperate from the high noise levels experienced in engine rooms and other high-noise regions of ships. Noise levels in rest areas must be low enough so that the effects of noise on sleep and overall crew performance are minimized. Figure 14 shows that the acoustical environment on cruise ships often receives most complaints.⁵²

Some A-weighted noise level criteria for crew rest areas are as low as 45 dB, while others permit levels as high as 60 dB in such areas. Noise levels in passenger spaces in ships are generally low enough that speech communication and sleep interference are not issues; providing passenger comfort is the predominant concern in this case. Acoustical prediction methods and the design of ships to achieve effective noise and vibration control are discussed in Chapter 101. Various studies have been made on the noise in ships.^{52–54} Studies have been made using sound intensity to identify noise sources in ships. In one shipboard study the sound intensity field was measured close to a double cabin window to try to identify the source of ship cabin noise problems.⁵³

1 INTRODUCTION

Interior noise in automobiles, buses, and trucks is caused primarily by the engine, exhaust, transmission, and driveline components (power train noise), tire/pavement interaction (road noise), and airflow around the vehicle (wind noise). From the source, vibration or sound energy is transferred by airborne or structure-borne paths to the passenger cabin interior. Generally speaking, structure-borne noise is the dominant component of vehicle interior total noise below 400 Hz, and airborne noise starts to become dominant above 400 Hz. For different applications, dominant noise sources or paths may be different. For example, power train noise is dominant during the accelerations of most vehicles; tire/road noise is the dominant noise source when a vehicle is cruising on a smooth road at about 80 km/h; and at high speeds of above 130 km/h, wind noise will surpass other noise sources and becomes the dominant noise source inside a vehicle. Testing and prediction are important to understand the cause of noise in the passenger cabin for a particular application and to optimize noise reduction methods. This chapter begins with a description of the primary sources of noise and vibration and how sound is transmitted to the passenger cabin of the vehicle. This discussion is followed by a summary of how test-based and computer-aided engineering (CAE) methods are applied to predict road noise, wind noise, and power train noise and to evaluate acoustic noise reduction solutions. The chapter closes with a summary of noise reduction methods currently used for automobile, bus, and truck applications.

2 VEHICLE NOISE SOURCES

2.1 Road Noise

Road noise is generated by events that occur at the tire/pavement interface. The source mechanisms are

complex and change depending on speed and the pavement and tire combination.^{1,2} Airborne sound radiation from the tread blocks and the sidewall of the tire can be a noise source for vehicles that do not have a well-sealed door and floor structure. Most of the time, road noise refers to structure-borne noise due to vibrations caused by vehicle tire/road surface impacts transmitted through the suspension mounts and that then excite the vehicle structure to generate low-frequency sound (<400 Hz). Tire/wheel imbalances can also introduce structure-borne road noise in the same fashion. Figure 1 shows a spectrogram of road noise of a typical vehicle. As can be seen in Fig. 1, the road noise of a typical vehicle is dominant at low frequencies (below 400 Hz). Tire ring noise (~260 Hz) can also be discerned with this vehicle.

2.2 Wind Noise

Wind noise is the dominant source of cabin noise at high vehicle speed (>130 km/h). As the noise treatments for engine noise and road noise become more and more efficient, wind noise starts to become a serious issue for all vehicle manufacturers. To study vehicle wind noise, vehicle manufacturers are using wind tunnels similar to the ones used in the aerospace industry. Some manufacturers even designed and built their own acoustically treated wind tunnels. Ford and Daimler Chrysler have recently invested in new quiet acoustical wind tunnel facilities for wind noise testing.³ Comprehensive reviews of wind noise have been organized by George,⁴ and George and Callister.⁵

The performance of vehicle door sealing systems is critical for the control of wind noise. At high speeds, the door on a vehicle tends to move outward due to the difference between the aerodynamic pressure outside

Figure 1 Typical vehicle road noise spectrogram. (The x axis represents time in seconds, and the y axis represents frequency, Hz.)

Figure 2 Wind noise level inside passenger compartment with and without aspiration.

the vehicle and that inside the cabin. If the door seal does not have enough ability to remain in tight contact with its mating surface, air can travel through the seal and cause aspiration. The loss of the seal material elasticity over time and the variation of the seal gap along the door perimeters can also cause aspiration to occur. From the dynamic performance point of view, if a seal takes a longer time to respond to its mating surface vibration, aspiration occurs. When aspiration

occurs, it is the most dominant source of wind noise in the passenger cabin. Figure 2 illustrates interior sound with and without aspiration.

Aspiration noise is a major wind noise concern, especially from the viewpoint of the passengers. Aspiration noise is usually broadband high-frequency noise; it is very directional and easily perceived by passengers inside a vehicle. Passengers may attribute aspiration noise to poor vehicle quality, whereas they will more

readily tolerate louder overall wind noise (other than aspiration), surmising that such noise has been caused by strong wind conditions outside the vehicle. To avoid aspiration noise situations, some vehicles have as many as three layers of seals. Low interior noise levels will not be achieved if aspiration occurs.

The next important source of wind noise is referred to as shape noise. A turbulent boundary layer is formed by the flow over a vehicle, with a large separated flow at the A-pillar, roof line, underbody, wheel wells, and rear of the vehicle. Aeroacoustic sound is generated by the turbulence in these separated flow regions. Aeroacoustic sound is treated as an acoustic source and transmitted into a vehicle's interior through a conventional noise transmission mechanism. Hydrodynamic pressure fields associated with these turbulent flows also load the surfaces of the vehicle. The hydrodynamic flow is treated as a dynamic pressure loading on the surface of the vehicle and causes the vehicle surface to vibrate and to generate structure-borne noise, which directly radiates into the vehicle interior.

2.3 Power Train Noise

Power train noise includes sound from all sources associated with generating and supplying power to move the vehicle, except the tires and brakes, which are covered separately. Power train sources include the engine, transmission, intake and exhaust system, and driveline. All of the power train components are both sound and vibration sources. The sound energy created by the vibration of the surfaces of these components and the aerodynamic loads within these components is radiated as airborne sound. The mechanical shaking forces and other vibration induced by the component are transmitted mechanically through the attachment points and structure-borne paths to the cabin.

For power train noise, all operating conditions are considered, including engine startup (cranking noise), idle conditions (stabilized warm idle), high-speed operation, and transient events such as engine runups [wide open throttle (WOT) or partial open throttle (POT) operation] and transmission shifts. The frequency range of interest for powertrain noise covers the entire range of human perception—approximately 20 to 20,000 Hz.

Figure 3 shows the engine noise of a typical vehicle measured in the passenger compartment when the vehicle is undergoing an engine runup in a WOT condition. Some discrete frequency lines are apparent in the engine WOT spectrogram. These lines represent sound spectrum peaks that are related to the engine speed or engine order changes during runup. These engine-order-related sounds dictate how an engine sounds during its operation. Many research studies have been focused on understanding how to design engine order sounds in order to create and enhance vehicle brand images.

3 NOISE AND VIBRATION PATHS

Noise and vibration transmission from the source to the interior of the vehicle are commonly referred to as either structure-borne or airborne paths. Structure-borne paths are characterized by direct mechanical

connections through the structure to the panels on the surface of the passenger cabin where the energy is radiated as sound to the interior acoustical space. Airborne noise paths refer to cases in which sound generated outside the passenger cabin is transmitted through the vehicle panels to the interior space.

3.1 Structure-Borne Noise

Low-frequency road noise is a classic example of structure-borne noise. The interaction of the tire patch and the pavement is the source. Vibration of the tire is transmitted to the wheel and to the spindle. From the spindle, the vibration energy is transmitted through various paths consisting of many different combinations of suspension components, chassis members, and body panels. For different vehicles or different operating conditions, the dominant path may be different. The dominant path usually includes well-coupled components that are resonant at an excitation frequency of importance. For unibody automobiles, structure-borne noise tends to dominate road noise from 300 to 500 Hz and might be important up to 800 Hz, depending on the source and the vehicle design. For a body on frame vehicle, the structure-borne noise may be dominant only up to 300 Hz depending on the performance of the isolation system between the body and frame.

Structure-borne paths are also responsible for low-frequency engine noise including engine boom noise (<100 Hz) and engine moan noise (100 to 200 Hz). The shaking forces of the engine are transmitted through the engine mounts and into the chassis and vehicle body. On some occasions, the dynamic forces of other power train components are well coupled structurally to the panels surrounding the passenger cabin and will radiate sound into the cabin. Problems occur when exhaust system hangers, high-volume air-conditioning (HVAC) piping, electrical system wiring harnesses, or similar structures are poorly designed and efficiently couple vibration energy directly to passenger cabin panels. Such problems are usually unanticipated and must be resolved at the prototype stage. The coupling between the power train component excitation and the vehicle cabin cavity is also a significant source of vehicle interior low-frequency boom noise (<50 Hz).

3.2 Airborne Noise

Airborne sound transmission in automobiles, trucks, and buses is similar to transmission loss behavior in buildings. For road noise, the sound generated at the tire propagates under the vehicle and is transmitted by airborne paths through the floor panels. Road noise also propagates around the body of the vehicle and is transmitted through windows and passenger cabin panels. Sometimes, road noise travels through the engine compartment or trunk and is transmitted through body panels into the passenger cabin. Airborne noise tends to dominate the high-frequency band of road noise. It starts to become important at frequencies from 300 to 800 Hz depending on the vehicle design.

The sound radiated by power train components is also transmitted by airborne paths to the passenger

Figure 3 Typical vehicle interior engine noise with wide open throttle engine.

cabin. For example, sound from the engine, transmission, and intake manifold is transmitted through the dash panel. Sound from exhaust components is transmitted through floor panels.

Most wind noise is transmitted from the source to the cabin by airborne paths. Aspiration noise is generated directly in the cabin. Aeroacoustic sound is transmitted through glass and panels. Hydrodynamic loads cause sound radiation from the panels or glass that experience the dynamic pressure of the hydrodynamic loads.

4 CABIN NOISE CRITERIA

There are many different events that affect the user's evaluation of the quality of automobiles, trucks, or buses. The automotive industry still depends heavily on subjective evaluation of either trained experts or jury testing with perspective customers. However, a great deal of recent attention has been paid to the development of objective measures of noise, and such metrics are becoming more prevalent. Cabin noise is a competitive quality characteristic of automobiles. Thus, thresholds

and criteria are largely company specific. Also, different objective measures are used for various events because they correlate better to customer preferences. A set of example events and criteria used include:

Road noise: Overall level, spectrum levels, speech intelligibility

Wind Noise: Overall level, spectrum levels, directionality, impulsiveness

Power Train Noise: Overall level, speech intelligibility, order tracking

It is still common to use A-weighted sound pressure level as an objective measure for some applications, particularly stationary events such as road and wind noise. The overall level is often decomposed into a frequency spectrum when diagnostic information is desired.

It is worthwhile to note that many large vehicle manufacturers are increasingly using psychological-acoustics terms to better correlate their vehicle quality

Figure 4 Frequency response function between force excitation at the spindle and sound pressure at the driver's ear location for 98 nominally identical Isuzu Rodeo vehicles. (From Ref. 8. Reprinted with permission.)

to customer perceptions. In these types of studies, loudness, sharpness, roughness, and pitch variation are often used to describe the product performance. Many of the vehicle original equipment manufacturer (OEM) researchers are developing their own metrics for the purpose of product evaluations.

Comparison of sound pressure level is widely used to evaluate power train noise. However, sound quality metrics are increasingly used, especially for luxury vehicles. Based on human perception studies, targets for various engine harmonics are set so that an ideal overall sound signature of the power train is achieved to meet the vehicle's marketing image—for example, sporty, safe, reliable, and so forth.^{6,7} Desired signatures can be achieved either through passive design changes, primarily through intake and exhaust system design, or by active means through sound cancellation and/or addition. To improve the sound quality of the power plant, unwanted power train noise—for example, gear whine—must be reduced in level sufficiently so that it is masked by the desired sound.

Speech interference indices are sometimes used to assess the ability of the customers in the vehicle to hold a conversation or listen to music during vehicle operation. Transient events, such as power train runups, require specialized metrics. Door slam, wiper noise, and road impact events are all important quality characteristics of automobiles and require specialized description to characterize a customer's evaluation of the vehicle.

5 PREDICTION METHODS

The purpose of testing and analysis is either to assess and understand the behavior of existing hardware,

particularly if noise performance goals are not met, or to optimize the design of future vehicles. One key issue for automobiles, trucks, and buses, and one that will be emphasized in this discussion because it is pervasive, is to accomplish these predictions in the presence of variation.^{8–10} Typical variation is illustrated in Fig. 4. This type of variation occurs in all automotive vehicle applications and must be accounted for when implementing test or prediction.

Because automobiles, trucks, and buses are relatively complex, testing and prediction for NVH characteristics is a significant challenge with current tools. NVH stands for noise, vibration, and harshness. While the terms noise and vibration are familiar to most, harshness is a relatively specialized term that describes the perception of a vehicle product. Harshness describes the total sound and vibration a customer feels when he or she operates a vehicle. A harsh vehicle would be one that gives rise to a sensation of one with hard tires, which would give the impression of a harsh ride. A quality operating system (QOS) for test and prediction is critical for improving the performance of noise and vibration prediction process over time. A QOS is used to provide a historical basis for how well a process performed in the past to avoid repeating the same mistakes. The QOS should include formal validation exercises and ongoing performance checking of the tools used to make noise and vibration prediction assessments. The quality of the data should drive the decision-making process.

5.1 Test-Based Methods

A nonexhaustive list of test-based tools used in automotive applications includes:

Road test	Structural damping
Wind tunnel testing	Laser doppler vibrometer
Wide open throttle	Modal analysis
Idle test	Operating deflection shape
Acoustical holography	Transfer path analysis
Acoustic reciprocity	Shaker testing/hammer testing
Acoustic absorption	Point and transfer mobilities
Acoustic intensity	Static sealing
Sound power testing	Static stiffness
Reverberation room	Chassis dynamometer
Transmission suite	Power Train dynamometer
Noise reduction testing	Test-based SEA
Acoustic reciprocity	Pass-by testing
Laser holographic interferometry	

Many of these methods are discussed in other chapters. In this chapter, the focus of the discussion will be on the best practice for the most common methods applied to automobiles, trucks, and buses.

For test-based approaches, transfer function analysis is often coupled with a body panel contribution analysis. The panel motions are correlated with the forcing functions to determine which motions are contributing to sound in the passenger cabin interior. This is accomplished with either an array of accelerometers or with a scanning laser.

An experimental transfer path modeling approach is often used for predictive models and path identification since the source, path, and receiver are typically independent for this application.^{11–13} Improvements are achieved either at the source or by reducing, or in some cases increasing, the magnitude of the transfer path.

Chassis roll testing is often used to simulate road events. Large-diameter rollers are used to make the surface appear as flat as possible. Both smooth surface rollers and replicate castings of rough road surfaces are used. This provides a controlled environment for road noise testing.

Because of the complexity of the vehicles involved and the variability in the vehicles, systematic and formal testing processes are important. There are two main strategies for testing: One factor at a time testing (OFT) and design of experiments (DoE). Both strategies are common. In either case it is necessary to design the experiment to resolve the effect of interest in the presence of the natural variation in the product. The testing should be conducted in a fashion that is robust to significant variation across the ensemble to be able to discriminate against the variation. One means of identifying sources of variation in test procedures is to do *component variance studies*.^{14,15} Once measurement variation is reduced as much as practical, it is important to periodically check that the test process continues to conform to the measurement quality standard.

Proponents of the OFT approach chose this method to simplify the process of determining which factor is

responsible for the change in the response. However, this approach ignores interactions between factors whereby one factor may depend on the setting or value of another factor. The OFT approach is also not efficient. As each factor is studied in turn, data collected to study other factors is ignored. Each set of data supplies information on only one factor.

Experiment designs (e.g., factorial) provide an alternative to the OFT approach. These designs allow the study of interactions between factors. The structure of factorial designs allows all the data from the experiment to be used to study each factor, which results in a significant increase in efficiency over OFT. The interested reader is directed to references on experimental design.^{16,17} Most of the experiment design literature discusses single-number response variables. However, the same data collection and analysis techniques documented in the literature can be applied spectral band by spectral band.^{18,19}

5.2 CAE-Based Methods

The CAE-based tools used in automotive noise and vibration prediction include (not exhaustive):

Finite element analysis	Computational fluid dynamics
Finite difference techniques	Acoustic ray tracing
Boundary element analysis	Analytical solutions
Statistical energy analysis	Porous element FEM

Most of these methods have been discussed in detail in other chapters. In this chapter the application of the most common methods for analysis of automobiles, trucks, and buses will be discussed.

When using analysis to assess program performance, it is important to understand how well the numerical model represents the hardware. Generally, this is accomplished by doing correlation studies. A corporate process controlled by a quality operating system is important to provide a historical perspective about analysis performance so every model does not require ongoing correlation. Important components of the quality operating system include capturing the performance of the models and charting the results at the end of the analysis effort. This allows statistical process control techniques to be applied to the analysis process to identify common and special case variation in the analysis process.

It is also possible to assess the ability of analysis to span the design space. This assessment is accomplished by comparing the predicted design sensitivities to those obtained from OFT or designed experiments. These data provide confidence that analytical results will provide meaningful data when used in optimization studies for configurations where correlation is not possible.

Finite element models (FEM) and Statistical energy analysis (SEA) are used most widely for noise and vibration prediction. The unique aspects of application of these methods to automotive applications will be discussed.

Figure 5 Illustration of a vehicle FEM model (element size = 250,000).

5.2.1 Finite Element Analysis Noise and vibration prediction models of automotive vehicles for the frequency band of interest are generally large. The time and effort required for creating and exercising finite element analysis for noise and vibration prediction of vehicles is dominated by development and validation of body models, often with over 250,000 elements. (See Fig. 5.) Here, the quality operating system becomes vital for managing the data for highly detailed geometry, property values, plus the connectivity of the model parts. In general, the quality operating system should also be used to supervise the relationship between model building and analysis software, even when the codes are provided by the same vendor.

Because of the large number of elements in these finite element models, most analyses are limited to linear approximations of the body and other major structural components. Even so, the computational effort is large enough that model reduction is necessary.^{20,21} Dynamic reduction and component mode synthesis,²² as well as tools for reusing previous results when analyzing changes, are widely used for automotive applications. For example, modal superposition methods are widely used to reduce finite element models from several hundred thousand physical degrees of freedom (DOF) to a few thousand modal DOF for vehicle or body or a few dozen modal degrees of freedom for simple components such as control arms. Finite element models are discussed in Chapter 7.

Finite and boundary element models have also been developed to predict the performance of the composite acoustical material systems used for noise reduction in passenger cabins.^{23–26} These models are used to predict wave propagation behavior in acoustical materials and the structural backing plates. The resulting model is either incorporated into the deterministic FEM method of the vehicle or noise reduction properties are derived to be incorporated into SEA models.

Vehicle level models are used to compute the response of the vehicle to sinusoidal or random inputs in the form of either applied loads or enforced displacements. These frequency responses are processed to evaluate performance. The quality operating system should be used to address how the bridge is built between CAE-based prediction and objectives that are based on true performance improvement.

5.2.2 Statistical Energy Analysis Application of SEA models in the automotive industry began in approximately 1986. Currently, this technology is in widespread use across the vehicle manufacturer and

supplier base. Commercial codes with extensive pre-processing capabilities have been developed primarily for automotive applications. SEA technology is capable of both airborne and structure-borne modeling. The most extensive use of SEA is for modeling airborne noise transmission into the vehicle interior. A review of SEA modeling for automotive applications can be found in the references.^{27,28}

The SEA models in use today tend to be full vehicle models. Having a full vehicle model allows for simulation of events such as four-tire airborne noise. It also allows for multievent optimization of the noise control treatments. As a result, the industry trend is to have a general full vehicle SEA model, which is modified to the particular properties of a vehicle, rather than a single-use model or partial model.

For an SEA model, the vehicle structure is idealized into mode groups along natural boundaries where possible. Body panels and the greenhouse glass are modeled as plate bending and inplane mode groups. The body structure, such as the pillars and the rocker panels, tend to be modeled as beams at low frequencies and transition to plates at higher frequencies. Subsystem boundaries tend to be at natural changes in impedance for the body structure. For example, joints would occur at the B-pillar or the front rail at the shocktower. The interior cabin space is often subdivided into several different acoustic mode groups. An SEA model describes how energy is transferred among different systems outside and inside a vehicle. A typical vehicle SEA model is composed of three parts: a vehicle interior model, vehicle structural model, and vehicle exterior model. For a steady-state SEA, the analytical solution requires simply that the input power must equal the output power for each acoustic or structural subsystem in each frequency band. Steady-state and transient SEA models are discussed in Chapter 17.

Transient SEA analysis at its most basic level simply includes time-dependent terms in the power flow balance equations. Although this may not at first seem to significantly add to the complexity of the solution, in actuality, the adoption of a numerical method is required for a transient solution. In this numerical method, each time step is solved as a function of the energy in each subsystem during the previous time step and of the change in energy with respect to time. So a solution technique that is purely analytical and closed form for a steady-state solution needs to use a numerical approach when a transient solution is calculated.

Statistical energy analysis models have been successfully applied to airborne noise reduction events. These events include engine noise reduction, induction noise, tire noise reduction, and interior noise due to exhaust noise. SEA modeling for wind noise is actively being pursued as well.³¹ Transient SEA for modeling vehicle transient sound phenomenon has been developed for modeling impact sound events such as door slams.²⁹ SEA for structure-borne events is not being as actively pursued at this time. The analyst community

Figure 6 Typical SEA models (including vehicle interior, structural, and exterior models).

tends to use deterministic methods such as the finite element method for structure-borne events.

Figure 6 shows the SEA models for a sports utility vehicle. The complete vehicle model includes separate SEA models for interior, structure, and exterior. There are two distinct ways to represent the sound package in current SEA models. One way is to explicitly model the sound package layout (pure CAE modeling). This is accomplished by representing the substrate as a plate bending subsystem and modeling the acoustic modes in the interstitial air in the fiber/foam material as an isothermal acoustic space. The carpet/barrier is modeled as either a limp mass or a bending subsystem with appropriate properties.^{30,31} The alternative modeling scheme is to use test/analysis data for the layout and import the consolidated properties as a transmission loss into the SEA model (CAE/test hybrid method). Data for the structure-borne noise reduction is also provided for coupling the plate vibration to the acoustic space. The hybrid method often yields more reliable predictions at low frequencies where model densities of the SEA systems are low and less accurate. Both pure CAE and CAE test techniques are in active use.

Statistical energy analysis models have been subject to rigorous validation.^{32–35} These model validations include:

1. Component impedance comparison (modal density)
2. Component testing (e.g., barrier TL measurements)
3. Damping measurements
4. Acoustic intensity scans
5. Response plot comparisons
6. Thermogram comparisons (test based—analytical)
7. Doe sensitivity assessment
8. Source determination
9. Hardware prove out—response comparisons

The SEA models have been shown to span the design space. Validations by both One Factor at a Time and designed experiment have been reported in the literature.^{30,35}

6 NOISE REDUCTION

Noise reduction strategies in automobiles, trucks, and buses include a large menu of potential solutions depending on the source, path, and application. In most cases, vehicles are sensitive to weight and cost and solutions must be highly efficient.

Noise reduction typically starts at the source. Suppliers of components usually face challenging specifications for noise. Most components, such as engines, motors, and tires, are becoming quieter while maintaining or improving performance and price.

The challenge of the vehicle manufacturer is usually to control the paths. The airborne paths are usually treated by closing up openings (i.e., with seals), adding mass to panels and windows, and adding sound absorption inside the passenger cabin. Structure-borne noise is treated by optimizing the mount (e.g., using isolators, impedance mismatch), damping of resonant systems, or building in vibration breaks. A few particular examples of noise reduction strategy applied to automobiles will be discussed.

A large proportion of the airborne noise in automobiles occurs in the front of the vehicle. Road noise, power train noise, exhaust noise, intake noise, front-end accessory drive noise, and wind noise are all transmitted through the dash panel, front floor panels, and windscreen glass. There are two main strategies for achieving noise reduction. The classical technique is to provide a mass backed isolation material over sheet metal surfaces to increase mass and improve transmission loss. Recently, similar noise reductions have been achieved with significantly reduced weight by eliminating the mass backed decoupling layer on the dash panel and significantly increasing the interior acoustic absorption. Another important strategy is minimizing the number of penetrations from the engine compartment to the interior. These penetrations include accelerator cable, brake, steering column, several heating ventilation and air-conditioning system penetrations, engine computer, and electrical cabling. Some vehicles have been designed to keep the number of penetrations to as few as 8. Less well designed vehicles can have as many as 18 penetrations through the dash panel. Managing the sealing of these penetrations and their associated noise control treatments is critical. The most important frequency range is in the critical speech intelligibility frequencies from 800 Hz to 4 kHz.

Other strategies for noise reduction include dash doublers, pillar sealers, damping materials in doors, door panels, and greenhouse glass. In a luxury car, the sealing systems/isolators are effective enough that the dominant acoustic path is the windscreen glass. In this case further noise reduction can be achieved by using laminated glass for the side windows as well as for the windshield and backlight glass. Laminated glass, due to its high internal damping, radiates

Figure 7 Wind noise in vehicle interior when laminated side windows are used.

much less sound when it vibrates. The multilayer structure of laminated glass also eliminates or shifts the coincidence frequency region of 2 to 3 kHz (the value for monolithic glass) and therefore yields a much better sound insulation performance. Figure 7 illustrates a typical wind noise performance improvement achieved by the use of laminated glass.

Interior acoustic absorption plays a significant role in noise reduction. There are several surfaces available for application of noise control treatments including the headliner, the seats, and the floor treatment.^{36,37}

For road noise, the noise reduction strategies in order of consideration are:

1. Optimizing point mobilities either using isolators or by structural design to minimize force transmission
2. Damping materials to minimize panel vibration
3. Sound insulation to block airborne noise paths
4. Tire geometry and properties to reduce source noise
5. Selective increases of the stiffness of body components

In general, body-on-frame vehicles are quieter than unibody vehicles because of an extra level of isolation (frame-to-cab isolation). However, some body-on-frame vehicles have poor performance in the low-frequency range because of flat body panels and minimal sound packages.

7 CONCLUSIONS

Automobile, bus, and truck NVH data show a trend of continuous improvement. New vehicles have been quieter than the models they have replaced. New tools and processes are being developed to meet these aggressive NVH targets.

Computer-aided engineering tools are being widely used across the manufacturing base to support automobile, bus, and truck noise issues. However, application of these techniques to automobiles, trucks, and buses is challenging. To be fully integrated into the design process, these techniques must account for the natural variation across the ensemble. And to effectively use these tools, a quality operating system must be implemented to continually learn from experience and achieve systematic improvement of both the modeling process and the resulting product.

CHAPTER 96

NOISE MANAGEMENT OF RAILCAR INTERIOR NOISE

Glenn H. Frommer
Mass Transit Railway Corporation
Kowloon Bay
Kowloon, Hong Kong

1 INTRODUCTION

With increasing rail services worldwide and passenger expectations for improved privacy and mobile telephones, noise inside railway cars is becoming an increasingly significant concern. This development presents a challenging task for the noise control engineer. Balancing the technical and commercial skills obtained from a wide variety of noise control applications is necessary for a cost-effective achievement of this requirement.

Well-tried methodologies to manage and achieve noise and vibration specification for railcars are now available. The use of such methodologies requires that the noise control engineer is completely knowledgeable about all relevant prediction and control techniques for noise and vibration control. These approaches can be used wherever commercial specifications for noise and vibration requirements are identified.

2 STANDARDS FOR NOISE CONTROL IN RAILCARS

While some minor changes to the final noise environment can be made once the vehicle is completed, it is not possible to reach the high levels of performance required for satisfactory speech intelligibility and privacy if the interior noise performance is not incorporated at the outset of the vehicle design. It is necessary to survey passenger expectations, consult possible levels of achievement with manufacturers, and agree on a set of practicable standards with the owner/operator before launching into the noise and vibration design.

For example, in Hong Kong, the Mass Transit Railway Corporation (MTRC) system regularly notes that about 7% of its passengers use a mobile telephone at any one time, and this is expected to increase with the widening use of third-generation (3G) mobile phone technology. For best speech intelligibility, it has been found that the A-weighted sound pressure level inside a railway car should not exceed 79 dB when traveling in a tunnel and 70 dB at top speed on open track. The reverberation time should also be kept short, between 0.6 and 1.0 s.

The specification used by the MTRC is given in Table 1¹ and has since become a standard for railway passenger car service in the Asia-Pacific region. These requirements were based primarily on English. However, further research has shown that speech intelligibility requirements are not very different for Cantonese and

Mandarin but should be checked for other languages.² At standstill the noise from the air-conditioning and ventilation system as well and the door opening and closing should be considered, as these could impact intelligibility and provoke an emergency evacuation.

Table 1 specifies target/acceptance A-weighted sound pressure levels with target levels slightly more restrictive than the acceptance levels. Experience with commercially driven noise and vibration design development has shown some safety factor should be included into the design process. Here the target/acceptance level provides that degree of design safety. In essence, the differences are a contractual means to incorporate imprecision and inaccuracy of the modeling and performance.

2.1 Safety Criticality

A noise control engineer tasked with establishing, delivering, and controlling the internal noise environment of a railway car must be able to work very closely with designers, consultants, manufacturers, and contract engineers. The noise control engineer must become familiar with the contractual requirements for

Table 1 Internal A-weighted Sound Level Specifications – Airport Express Train

Specification	Condition	Target/ Acceptance
	Test Method	
External top speed 135 km/h, braking and acceleration	ISO 3095	80/83 dB (135 km/h)
External 0 km/h – 7.5 m	ISO 3095	70/72 dB
Internal top speed – free field	ISO 3381	65/70 dB (135 km/h)
Internal top speed – tunnel	ISO 3381	74/79 dB (135 km/h)
Internal stand still	ISO 3381	60/65 dB
Door opening and closing	ISO 3095 and 3381	65/70 dB
T60 (125 Hz)	ISO 3382	1 s \pm 0.2 s
T60 (250–4 kHz)	ISO 3382	0.4 s \pm 0.2 s
RASTI		0.55 (minimum)

the rolling stock and, in particular, the requirements for the reliability, availability, maintainability, and safety (RAMS) of the vehicle fleet. These four factors are critical to safe operations of a railway, and there can be no compromise on passenger safety. There will be many and possibly significant changes to the vehicle design throughout the manufacturing process, and the noise control engineer must have his or her own consistent means of achieving the agreed upon internal noise specification.

2.2 Developing the Specification

There are essentially two methods of meeting the noise and vibration specification. The first requires the owner/operator to prescribe all steps and all specifications in detail. The advantage of this method is that the manufacturer can accurately price the work taking advantage of standard designs and components in a straightforward design and build contract. However, given that the new design of the rolling stock will probably change to meet RAMS requirements, this procedure has a high element of risk.

The second method is to prescribe noise and vibration performance contractually, including general outlines of the plans, submissions, and achievements that the manufacturer must provide during the continuing design and manufacture of the rolling stock. The owner/operator may perceive the above contract strategy as a means to gain confidence that the noise requirement would be met. On the other hand the manufacturer may perceive the contract strategy as a means to minimize and control the risks of not meeting the client's specification. A mature owner/operator would take advantage of both the confidence building and the risk control of the latter method and develop a commercially beneficial partnership. Care, however, must be taken to allocate the proper type of resources to the process and overall management regardless of the method chosen. The remainder of this chapter will follow the latter contractual methodology.

2.3 External Noise

It is an *a priori* assumption that the achievement and control of the specified internal noise values for the rolling stock are commensurate with maintaining a minimum external noise emission of the vehicle. In a typical rolling stock contract the maximum external noise levels at standstill and at maximum speed are specified as are the internal levels at both standstill and top speed. Recent changes in the International Organization for Standardization (ISO) standards for noise measurement of railcars reflect the need to standardize the roughness of the wheel-rail interface.³

Experience has concluded that a robust design philosophy is one where the external A-weighted sound pressure level emissions for all electrical and mechanical equipment shall be about 10 dB below that for the wheel and rail noise at top vehicle speed and during braking and acceleration. In addition the wheel and rail profiles and hardness as well as the track and primary vehicle bogie stiffness should be optimized and maintained for a minimum wear scenario.⁴ This is

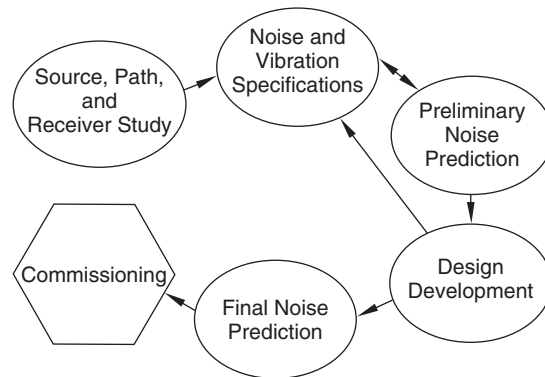

Figure 1 Noise assurance plan.

far from trivial and is outside the scope of this chapter. The reader is referred to descriptions of rolling noise simulations in the literature, for example, TWINS.¹⁵

3 NOISE ASSURANCE PLAN

The conceptual heart of the methodology is the noise assurance plan (NAP). Shown diagrammatically in Fig. 1, a requirement for the NAP is specified within the contract documents with the particular specification. The NAP contains six main stages: source-path-receiver study, noise and vibration specification, preliminary noise prediction, design development, final noise prediction, and commissioning.

3.1 Noise Management Plan (NMP)

The contractual arrangements for rolling stock will have particular stages connected to payments, and the noise control engineer must devise and implement a strategy for achieving the specified performance through a noise management plan. The management of the noise control must be structured to fit the overall contractual deliverables for the rolling stock while allowing the manufacturer the flexibility to design an acceptable low-noise vehicle. Thought must also be given as to level of manpower resources needed to achieve the desired noise performance as well as training other members of the design team.

A possible NMP, included as Table 2, shows how a proposed set of tasks can be grouped into particular rolling stock stages that can fit into an overall contractual program requirement for design, manufacturing, and commissioning. The tasking can also be used to determine the skills and remuneration for specialist subconsultants undertaking this work for the client or manufacturer. The task number and title shown in Table 2 allow a unique definition to fit into an overall contract program while permitting a description and verification of a deliverable for payment.

3.2 Source Pathway Receiver Considerations

In the first stage of the rolling stock contract, the manufacturer will propose and agree on the basic

Table 2 Noise Management Plan (NMP)

Rolling Stock Contract Stage		Task Number		Task Title
Number	Title

design, methodologies, and plans, stating how they will achieve the required level of RAMS. The noise control engineer must similarly require an NMP stating how the noise and vibration specifications will be met. Experience indicates that excessive detail is not overly beneficial at this juncture. The focus must be forming a team with a high level of practical experience. However, it is necessary that there is sufficient contractual authority and control given to noise control engineering to ensure that the final result will be achieved. With weight, performance, design, and power considerations, a firm but flexible hand is needed.

Once the detailed NMP is agreed upon, attention can then be focused on the achievement of the specification. A source–pathway–receiver study focuses on the various noise and vibration sources that exist within the rolling stock, as shown in Fig. 2. There are both airborne sources and structure-borne sources. Examples of the airborne noise are noise from the wheel–rail interface transmitted through the floor, walls, and roof and noise from the ventilation system. Examples of structure-borne noise are the reradiated noise through the vehicle floor, walls, and roof from the bogie and vibrating or rotating mechanical equipment and air turbulence from a pantograph reradiated through the roof and walls.

The emissions of each of the sources identified in Fig. 2 must be specified, controlled through prototype testing, subsystems testing, and during the final commissioning phase. General guidance on noise sources and pathways is given below.

3.3 Noise and Vibration Specification

From an understanding of the impact on the passengers, the source–path–receiver study implies values for the noise and vibration sources and transmission reduction and radiation values (Table 2, task 3). Together with a car body study and a preliminary prediction of reverberation time, this initial assumption results in a set of preliminary assumptions for the noise and vibration specification of the electrical and mechanical components of the vehicle. A listing of possible sources and pathways is given in Table 3.

3.4 Noise and Vibration Specification

Specifications for the main equipment should include sound pressure and or sound power levels as well as vibration levels in three dimensions. It is also essential to identify how the data will be tested

Table 3 Noise Specification

and analyzed (A-weighted, octave, or one-third-octave values), the relevant international norms and standards to be used, and who will be testing the equipment (approved laboratory, consultant, or manufacturer and their qualifications). Experience has shown that the specification should be written in two parts, a general specification detailing the standards and measurements methods and the particular specifications detailing the acceptance criteria. Note that this is a preliminary set of subsupplier specifications based on a number of design assumptions that must be confirmed and closed out in the further design development.

3.5 Preliminary Noise Prediction

A preliminary noise prediction will be concluded from the noise and vibration specification with the help of a predictive model (Table 2, task 7). Model use will be discussed in more detail below. At this time it is

most informative to provide noise level predictions along the length of the vehicle, as the owner/operator may allow noise levels directly over the bogey area to be slightly higher than noise levels in the middle of the car. The preliminary prediction not only indicates how successful the design will be at achieving the specification but will also indicate the critical design challenges to be faced in the systematic low-noise design task.

3.6 Design Development

The next stage in achieving the internal noise level will require that the contractor or his or her specialist consultant participates in the design development of the vehicle. As noted above, there may be significant discussions on the design of components to meet RAMS requirements and in particular a low-weight fire performance. Designs of the floor, walls,

and roof as well as electrical and mechanical subsystems and air-conditioning and ventilation systems may be redesigned. The noise control engineer must ensure that the materials to be used and their installation will meet the agreed performance. It is strongly recommended that a tracking mechanism for sources, materials, drawings, and installation methods be established at an early time in the design development process and audited at regular intervals during the design and manufacturing process.

3.7 Final Noise Prediction

Once the detailed design has been completed and Table 2, task 4, is approved, the finalized noise and vibration specification allows the manufacturer to purchase the specified equipment and material. However, throughout the manufacturing and subsupplier phase, the noise control engineer must ensure that the installations are correct and the subsystems function as required. Vigilance regarding design and specification changes in this stage through the engineer's instructions must also be weighed. As noted above, there is a need to track and audit the key subsystems, and the engineer may require tests for key elements of the vehicle; for example, the floating floor and silencers on the traction motor and the air-conditioning units (Table 2, tasks 16 and 17). The noise control engineer should be available to accept design changes during the tests and provide a proper paper trail. With confidence now at a high level, the commissioning tests should show compliance with the internal noise specification for the vehicle.

The noise control engineer must consider how to best present the results and estimations to higher management for decisions. Information will be presented both to the design team responsible for RAMS and perhaps to more senior management if decisions must be taken impacting cost, program, or future maintenance. The author has found the use of simple bar charts and graphs to be most helpful. Additionally, noise simulations are exceptionally useful. These employ internally recorded noise levels from vehicles that have been mixed to a sound quality that will mimic the pertinent predictions. While the use of complicated and detailed sound quality has not been used in this area previously, there is no doubt a possible benefit for the noise control engineer to exploit this technique.

A word of caution is, however, necessary. These simulations and predictions will typically be played in executive offices or meeting rooms and as a result may not give the psychologically relevant results that the noise control engineer may prefer. Forethought is needed to prepare the simulations accordingly.

3.8 Commissioning

The resources used in tracking individual components and the testing of subassemblies assure that the final product will generally achieve the specifications. While the intention is that there are no surprises at this point, there can be some surprises. Experience has taught that the assembly of the air-conditioning unit may present some unwanted structure-borne noise

issues, and a mismatch of the rotational frequency of the ventilation fans could create a low-frequency resonance experienced throughout the vehicle. The engineer should allow some additional resources for this last stage.

4 GENERAL DESIGN GUIDANCE

4.1 Mathematical Models

The prediction of the internal noise in a railway car will depend on many different forms of mathematical modeling. There are an increasing number of analytical models to predict internal noise within railway cars: Finite element modeling (FEM), boundary elements modeling (BEM), and statistical energy analysis (SEA) (see Chapters 7, 8, and 17). Rolling noise is predicted by TWINS and modeling of pantograph noise can be undertaken with computation fluid dynamic (CFD) modeling (see Chapter 7). Given the number of airborne and structure-borne sources, the modeling is difficult and imprecise, incorporating a number of assumptions, for example, coupling factors and damping. This raises doubt as to the robustness and veracity of any one approach.

Considering the complexity of the overall design, it is this author's experience that it is best to keep the models as simple as possible and use base modeling on measurable and controllable parameters. As a result those models based on the measurement of sound power and vibration levels of airborne and structure-borne sources, sound reduction, and radiation values in existing railway cars combined with spread-sheet transparency of results tend to give a more robust prediction than more theoretical approaches.⁶ However, the use of the more analytical methods to examine and optimize subsystem performance is advisable and cost effective. SEA is particularly helpful in prioritizing noise control efforts for maximum cost-effectiveness but is not suitable for the prediction of overall absolute noise levels.⁷

4.2 Validation

For railcars that are of newer design, the choice of model will be a critical one. One way of examining the robustness and sensitivity is to require validation of all modeling and or procedures within the tendering phase or in the stage 1 deliverable of the NAP (Table 2, task 2). Generally, the models should be able to predict the internal A-weighted sound pressure levels at any position within the vehicle to ± 2 dB with all external and internal conditions prescribed. The engineer must note that a validation requires a comparison between known and controllable inputs and measured outputs, for example, noise levels along the car. No "tuning" of the model should be allowed once the physical parameters of the railway car are input. Typically, a validation is proven on a previous project. There is much confusion with modelers with the erroneous assumption that verification is the same as a validation.⁸

4.3 Noise Sources

As detailed above, achievement of a low level of internal noise in railway cars will depend on the control

and mitigation of airborne and structure-borne noise sources with full cognizance of the RAMS requirement for the vehicle. Once the RAMS targets and the means to meet the targets are agreed, there should remain significant flexibility allowing the noise control engineer to meet his or her goal.

There are three major speed regimes regarding external noise generation:

- From 5 to approximately 50 km/h, the propulsion noise will dominate and will increase by approximately 10 log(vehicle speed).
- From 50 to approximately 220 km/h, the main noise source will be the wheel–rail interface with noise for disk-braked vehicles increasing roughly as 25 log(vehicle speed).
- Above 220 km/h, air turbulence will be the dominant source and will increase as 80 log(vehicle speed).⁹

For most intercity and mass-transit trains, the dominant airborne noise source will be the wheel–rail interface or rolling noise.

Within the bogie there are essentially two levels of vibration control: a primary and a secondary suspension. It is the secondary suspension that provides the ride quality of the vehicle while the primary suspension controls the car body motion. Both suspensions will effect the transmission of vibration from the wheel–rail interface and the propulsion system into the vehicle through the center pin, as will any further connection of the bogie to the vehicle frame, antiroll bars, and horizontal dampers.

An essential element of the control of the wheel–rail or rolling noise is to ensure that the tread surface of the wheel and the contact patch on the rail is as smooth as practically possible. For the rail this can be achieved by regular grinding and for the wheel by regular turning and lubrication of the wheel flange. The regularity of grinding and wheel turning is dependent on the operational characteristics and economics of the system. Rail maintenance models are normally used to predict the optimal maintenance conditions.¹⁰

It is best to employ disk brakes rather than tread brakes to maintain the smoothest wheel tread. Tread brakes can cause wheel flats and roughen the running surface of the wheel. The increased wheel roughness gives an increased mechanism to excite the natural modes of the wheel and exacerbate rail vibration. Wheel profiles and to some extent rail profiles can be designed to minimize airborne noise emissions. However, the rail industry tends to be conservative, and the use of unusual designs will take some time for acceptance.

The second important factor is the use of continuously welded rail. Rails with fish plates or bolted connections between rails will cause the well-known clickity-clack noise that could defeat even the best low-noise railway car design.

Another area of focus is the propulsion system consisting of the traction motor, gearbox, and the coupling. Most common traction motors rely on air cooling for controlling the motor temperature.

Excessively high temperatures will cause bearing and insulation failure and possibly an underfloor fire. Typically near the exit of the motor, the fan will draw cool air in over the internal structures of the motor and exhaust the hot air. This can be very noisy and contain pure tones if the fan is not designed correctly. The better fan designs include variably spaced blades where attention has been placed on the blade edge design. A good design can essentially remove all pure tones from the fan noise spectrum, and attention to individual blades design can provide an additional 3 dB to 5 dB attenuation in the A-weighted noise level.

Nonetheless, the noise from the traction motor is generally very high, and additional silencing is needed both on the inlet and exit of the traction motor. The design of the silencing is difficult since it must provide an A-weighted noise level attenuation of 10 dB to 15 dB, while not significantly increasing the pressure drop through the motor, and be easily demountable for thorough maintenance. An increased pressure drop will cause increased heating exacerbating bearing wear. It has been found best to work with the traction motor manufacturer, establishing a test facility where sound power from the motor can be readily measured and combine this with the possibility for building and testing various silencer designs. Silencing material can either be fiberglass, mineral wool, or sintered aluminum with the choice of the material dependent on the cost and application. Maintenance aspects must also be considered.⁴

The gearbox is another key noise source. The use of FEM for gearbox design can be very beneficial in determining the thickness of the material and optimizing the gearbox weight. The design of the gearbox should ensure that there are no gear meshing frequencies close to any of the natural frequencies for the gearbox itself. If there are, the pure tones from the natural gear meshing frequency will be emitted as airborne noise and could enter the vehicle.

The design of the air-conditioning and or heating systems will depend on the requirement for passenger fresh air. A general rule is to supply of the order of 3 litres/second/passenger. It is also suggested that the issue of thermal comfort is considered in the overall design of the railway vehicle. Generally, fresh air is taken in through the bulkheads and through the overhead vents in the air-conditioning or ventilation system. Heating is supplied in the foot panels. However, fresh air inlets will be a noise source particularly in tunnels. The fresh air channels in the car bulkheads must be designed with the appropriate mitigation and packaged with mineral wool or fiberglass.

A vehicle may have two air-conditioning or ventilation units on opposite ends of the vehicle roof, incorporating the use of vehicle return air and blending this with a fresh air source. The units are self-contained consisting of exhaust and evaporator fans, a compressor, coolant storage, and heat exchanger. The units feed into a set of ducts such that both units supply the middle of the vehicle while only one unit supplies each end. The airflow through the ducts and the ventilation outlets must also be noise controlled as must the break-out noise from the

underside of the unit and ducts. There is also a challenge to control of the vibration and reradiation of noise from the compressor and fans. Caution must again be exercised in that noise attenuation does not prohibit adequate airflow to passengers. There are not a large number of air-conditioner manufacturers that include noise and vibration requirements into their performance specification and as such the noise control engineer has a huge task to ensure compliance to the noise and vibration specification. Note that there are other environmental restrictions in place regarding the choice of coolant and use of additives to transformer oils.

4.4 Sound transmission

Given the air and structure-borne sources noted above, achievement of a controlled and low internal noise level will depend on the success in implementing a “box within a box” construction philosophy. Well-known from isolation treatments and aircraft and ships, the internal environment within the railway car must be as mechanically independent from the outside structure as practical. However, the need to provide safe, cost-effective, light-weight structures while safely including all of the electrical and mechanical services is demanding. There is a need to balance the sound transmission and the sound radiation capabilities of the surfaces.

The sound transmission through the vehicle floor, doors, windows, roofing, and bellows between vehicles are key elements. As noted above analytical models can assist in the design of the floor. However, attention is needed to provide a design that is safe for fire protection as well as mechanically coherent. Typical sound transmission control (STC) values for flooring for low values of internal noise will be in the upper 40 to low 50 dB. This is typically a double-walled construction with plywood internal flooring placed on rubber blocks supported by steel or aluminum profiles with beams—a floating floor. The design of the floating floor will depend on the chosen elastic material and floor design. Weight must be minimized. The rubber used must have fire retarding properties as well as the preferred elastic properties to ensure a proper overall high value of sound transmission class. There will also be many cables and possibly hydraulic piping through or directly attached to the underside of the floor. All attachments shall be elastic wherever possible to avoid the transmission of vibrations along the vehicle. Care must be taken to ensure that resonances are well damped.

The design of the internal walls of the vehicle is likewise important. Where possible this should be a double-wall construction. However, due to the structural and mechanical requirements on the walls, some walls are made with a honeycomb core, similar to marine bulkheads. The detailed connection between the flooring and the wall including the connections between the seats, the wall, and the floor is likewise critical.

Window construction is typically double-walled windows. These can have asymmetrically thick glass and possibly contain a rare gas to increase the noise transmission loss. Detailed care in the connection of the window to the wall is essential to avoid

any openings and to minimize vibration transmission between the walls and windows.

The doors must be designed to compromise the conflicting requirements between mechanical requirement to withstand forces from passenger movement and the flexibility for high noise reduction. Sliding or plug doors can be used for a low-noise design, but the future maintenance will be much less for the plugged doors. Doors tend to be a single-leaf construction, and the use of handles within the doors for maintenance access further increases noise transmission. Another critical factor is the rubber trim between doors and the vehicle body. Gaps will provide a source for airborne noise to enter the car and will become worn more quickly with sliding doors.

The design of the driver's cab also deserves special mention. The client should include additional noise control criteria in the cab referring to occupational health and safety requirements. In addition to all of the noise sources noted above, there is an additional noise source through the windscreen and possibly through a separate ventilation or air-conditioning system. Some adjustments may need to be made on-site in a mock-up to examine the placement and connection of the installed equipment.

4.5 Reverberation Control

In predicting the internal noise of the vehicle, it is also necessary to treat adequately the surfaces for a controlled reverberation time while at the same time ensuring these surfaces are maintainable without fire loading or excessive cost. For example, the simulations accurately represent the effects of sound absorption on the vehicle ceiling and the effect of cushioned seats. There are a number of standard software packages available, and they will all display similar trends. However, given the fact that the reverberation times are 1 s and below and that there are many reflecting services within the vehicle, modeling should be applied cautiously.

4.6 Fabrication

A value engineering process is normally undertaken to optimize the design and manufacturing process as the final component of the detailed design prior to fabrication. This may present challenges to the low-noise design, and the noise control engineer must ensure that the tracking process established earlier is sufficiently robust to maintain the essential elements of the low-noise design. This refers to the materials, their performance, the installation, and their fixation.

The author has found it most useful to incorporate testing on subsystem prototypes and one of the prototype vehicles at an early stage in fabrication. This needs to be specified within the NMP, usually in stage 3. The testing uses a large shaker to provide vibrations to the steering pin of the bogey and loudspeakers to provide airborne noise. Typically, the internal noise levels of the vehicle will be checked along with vibrations of surfaces. Sound intensity measurements will be required to measure the sound transmission and determine the sound radiation of some surfaces.

4.7 Commissioning and Maintenance

The final stage of the NAP is the commissioning tests. These tests will identify the noise levels within the cab and throughout the railway cars. It is essential that the surface of the wheels and the rails are prepared accordingly to provide the appropriate running surfaces. It is normal to include descriptions for the wheel and track within the specifications for the rolling stock should testing be undertaken by the manufacturer. As a final deliverable, the manufacturer or owner/operator should establish fleet averages and variations for the different car types.

The internal noise of the vehicle will change as the railway ages. A railway car can be operated for 30 years and with upgrading 40 years. A railway operator will normally have a planned rolling stock maintenance regime with different types of maintenance undertaken at regular intervals. A best practice is to maintain the noise control measures as well, allowing only a small degradation of the internal noise levels. The degradation of internal noise levels will mostly depend on the state of the ventilation and air-conditioning system and the rubber trim around the doors and possibly windows. The exhaust or ventilation fans could be operating at slightly different speeds and gaps could be forming in the rubber trim. It is best practice to monitor the internal noise levels regularly and schedule maintenance accordingly.

Given the attention and care to internal noise performance throughout the vehicle lifetime, the railway operator can look forward to a cost-effective operation with satisfied regular customers.

CHAPTER 97

INTERIOR NOISE IN RAILWAY VEHICLES – PREDICTION AND CONTROL

Henrik W. Thrane
Ødegaard & Danneskiold-Samsøe
Copenhagen, Denmark

1 INTRODUCTION

The interior noise level in a railway vehicle is one of the key parameters for the comfort of the passengers. It is therefore important to apply the principles of low noise early on in the design, both to ensure that the desired noise level is achieved and to minimize the cost of low-noise design. A large number of noise sources and paths, both airborne and structure borne, are present in modern railway vehicles. The contribution from the structure-borne paths is normally dominant in the low-frequency range, while the contribution of the airborne paths usually dominates in the middle and high frequencies. The acoustical strength of the noise sources can be controlled by means of specifications. The overall acoustical design is often optimized by applying prediction models based mainly on a statistical energy analysis approach. Optimization of the transmission of structure-borne noise from the equipment to the car body is usually made using finite element modeling techniques. The contribution from aeroacoustic sources is a special topic mainly of relevance for high-speed vehicles and is not the main concern in the control of noise in rapid transit railway vehicles.

2 ACOUSTIC DESIGN PROCESS

The acoustical design process, from the conceptual design of the vehicle through to the production stage, consists of a number of separate tasks, as described in detail below. The acoustical design process also involves noise management in the form of a noise assurance plan describing the process, responsibilities, and methods of corrective action as covered in Chapter 96.

2.1 Noise Specifications

The basis for the whole design process is naturally the target internal noise level. Today the noise levels in the public spaces of the vehicle normally fall below legal or official limits. Consequently, the desired noise levels, when developing a new train type, can be set according to the train manufacturers estimate of which noise levels meet present-day standards. More often a client, for example, an operator, prepares the noise specifications.

Legal limits or limits set forward by trade unions may apply when considering the noise exposure of the driver. With the exception of the noise problems related to the driver's cab of diesel locomotives,

driver's cab noise issues are more a matter of providing a proper working environment for intellectual work than of preventing hearing damage.

When measuring the noise level, it is preferable to use the equivalent continuous A-weighted sound pressure level, L_{pAeqT} , (averaged over typically 5 to 10 s) rather than the maximum noise level, L_{pAFmax} or L_{pASmax} (maximum level during short time). The continuous level gives a much more statistically stable result than the second where a single event will determine the noise level. The latter is not a good descriptor of the overall noise level in the train.

It is not fully certain whether the A-weighted sound pressure level provides a good correlation to the sound quality experienced by the passengers.¹ Dedicated specification of sound quality parameters is not yet standard and is normally limited to expressions like "rattling noise must not be present."

In addition to the above parameters, limits for the presence of pure tones and impulses are often specified, typically as a level penalty based on rules originating from evaluation of annoyance caused by pure tones and impulses in the environment. The internal noise specification should include a description of the roughness of the rails as function of wavelength in the range 0.01 to 0.2 m at the test site for the noise measurements. If this is not the case, the roughness levels have to be defined at the onset of the acoustical design.

Over the years a trend toward demanding still lower levels has been observed. Very low noise levels affect the mass and cost of the vehicle, so the question regarding reasonable noise levels should be raised. An optimum acoustical comfort is supposedly achieved when the variations in the noise level during a journey is kept small, as stated in Ref. 2. This means that the difference between standstill noise levels and driving noise levels should be reduced. Likewise the very low noise levels found in trains designed for a speed of, for example, 180 km/h but running at 100 km/h when used in local traffic, result in reduced comfort due to lack of privacy and to information-carrying background noise (passenger conversation or use of cellular phones). A possible solution could be to utilize the public address (PA) system or the high-volume air-conditioning (HVAC) system to provide masking noise. A noise level that provides a reasonable compromise between privacy and speech interference is generally considered to be the optimum noise level.

Table 1 Checklist for Tender Documents

Cause	Effect
Low floor designs	Insufficient height for floor construction
Low floor height/big wheel diameter	Insufficient height for floor construction
External/internal dimension ratio	Insufficient width for wall construction
Low weight	Need for double constructions with sufficient building height
Layout	Low-noise area above major noise sources
Layout	Acoustically weak components located close to noise sources
Design, internal	No separation between noisy and low-noise areas
Design, internal	Restrictions in use of absorbing panels
Design, external	Restrictions in use of skirts
Material selection	Restrictions in use of optimal acoustical materials
Aluminum profiles for car body	Low mass-to-sound-transmission ratio
Seat selection	Insufficient sound absorption
Fire requirements	Restrictions in use of optimal acoustical materials
Vandalism protection	Restrictions in use of optimal acoustical constructions, e.g., seats
Choice of equipment	Client specification of noisy components, e.g., self-ventilated motors, piston compressors

It seems that an A-weighted noise level of 65 to 68 dB should be the target.

With the currently used layout of trains with no or very few internal doors, a significant jump in the specified noise level is not possible (e.g., for a compartment adjacent to a vestibule and the vestibule). The reason being, even with highly absorbing interiors, only a limited lengthwise attenuation of the noise level of the order of 1 to 2 dB per metre is possible. This fact can result in the specified level in the compartment determining the acceptable level in the vestibule. The consequence could be a requirement to install thicker, heavier, and more expensive external doors.

One solution to this problem, which is even more severe in the intercommunication gangway area, is to install internal doors or to accept that the noise level in the passenger area close to the vestibule or gangway is higher than in the rest of the compartment.

2.2 Equipment Specifications

The internal noise levels are determined by a great number of factors, including the airborne and structure-borne noise source strength of the equipment used on the train. Therefore equipment specifications have to be prepared to set targets for the noise and vibration design by subsuppliers. The task of setting limits for the allowable contribution for each type of equipment is difficult and has to be based on a proper balance between the different equipment, using information of source strength for state-of-the-art equipment. For further discussions of handling equipment specifications see Chapter 96.

2.3 Conflicting Requirements

As an interaction is present, the acoustical requirement should not be separated from other requirements of the train: reliability, availability, maintainability, and safety (RAMS). For example, when setting a floor height above head of rail and a wheel diameter, the allowable construction height of the floor has also been defined. The allowable space for the floor has a major

impact on the noise properties of the whole car, a fact that sometimes is not recognized. A related problem is found in the articulation area of low floor trams where the restricted space most often hinders use of the more efficient double-wall construction, thereby resulting in an insufficient sound transmission loss of the construction. These space restrictions inherently lead to a conflict relative to the mass of the vehicle, as lack of space calls for heavier constructions. Table 1 summarizes some of the conflicts that should be examined at the tendering phase, and then followed by corrective action as needed.

3 PREDICTIONS OF INTERNAL NOISE

When predicting internal noise, it is necessary to describe both the airborne and the structure-borne source properties, as opposed to external noise problems where only the airborne noise is considered. Two types of propagation paths thus exist, which are treated separately. For example, a separation into convenient subpaths could yield:

- Sound power of source to sound pressure outside the train, for example, a window
- Transmission through the window
- Radiated sound power from inside of window to noise level in train

The structure-borne path is usually treated in a similar way using several subpaths. Unlike the airborne noise, the structure-borne noise is considered independent of the external acoustical environment (e.g., running in a tunnel).

4 PREDICTION METHODS

A number of analytic tools are available for the prediction of the internal noise level: statistical energy analysis (SEA), boundary element modeling (BEM), and finite element modeling (FEM). An analytic model of a complete railway vehicle becomes extremely large

in number of subsystems or elements. The resulting complexity makes it difficult to maintain the necessary overview.³ Furthermore, a great number of details are not defined at the outset, indicating that use of BEM or FEM models cannot be justified. For SEA models, a violation of the assumption of weakly coupled structures cannot be avoided, especially when using the SEA model for external and internal air volumes. Therefore, use of semiempirical tools seems to be advantageous for modeling of complete cars. SEA and FEM models are, however, considered to be extremely helpful to optimize subsystems.

Semiempirical tools work by dividing the car into sections along the car body and into levels in the vertical direction. This results in several elements, one or more at each section and level. For the airborne noise, the sound pressure level on the outer side of each element is determined based on the geometry of the car body and the position of the individual noise sources. The contribution to the internal noise level from each element is determined from the sound pressure level over the element and the airborne noise transmission loss. Likewise the structure-borne noise level of each element is calculated on the basis of the propagation loss of the car body structure and the coupling loss from, for example, the car body sidewall to the interior trim. The structure-borne radiated noise from each element is then calculated based on the structure-borne vibration level of the element and the radiation index of the element. The total sound power radiated to the inside of the car is found by a summation of the airborne and structure-borne contributions from all elements. The resulting sound pressure level distribution can then be calculated using a dedicated room acoustic ray-tracing/image source modeling program as, for example, discussed in Ref. 4. This kind of modeling is said to be semiempirical because it is based on classical vibroacoustic calculations, subsequently verified and adjusted by means of measurements.

In the case of early concept studies or quick checks of the airborne noise contribution from critical elements close to the source, a rough estimation can be made using the difference of the A-weighted total level for the source strength and the weighted sound transmission loss for the element in question. For the detailed studies the modeling is normally done using octave bands. In the opinion of this author the statistical uncertainty of the underlying data does not justify a modeling in, for example, one-third octave bands.

5 SOURCES

Data on the airborne and structure-borne source strength of the noise sources is needed as input to the model. Suppliers are sometimes able to provide the airborne noise source strength, but data on structure-borne noise is rarely available. This implies that the source strength has to be based on experience with similar constructions using data from a databank or using values from handbooks. The true source strength of the structure-borne sources, that is, the

power injected into the receiving structure, is quite difficult to establish.⁵ Therefore, the more simple approach of just using the free velocity level, L_v , of the mounting brackets as the descriptor is very often applied beneficially. The velocity level is used, since the sound pressure level is proportional to the velocity level. It is also possible to use the excitation forces as a descriptor, but this asks for a very complicated setup if the force shall be measured directly. A more complete description of the properties of the equipment in question is obtained when the complex mobility of the mounting brackets is known.

Table 2 gives an overview of the major sources and their relative importance. Diesel engines are included since these are used in both suburban trains and modern low-floor trams. Diesel engines can be mounted both as underfloor units and as roof-mounted units using a diesel-electric propulsion system.

As a rule of thumb, the velocity level of the structure-borne noise sources decreases with frequency while the level of the airborne noise sources generally peaks in the middle frequency range. Taking the airborne and structure-borne properties of the vehicle structure into account, the net result is that the contribution from structure-borne noise to the A-weighted noise level dominates in the frequency range up to 200 to 400 Hz. In the remainder of the frequency range the airborne noise is normally dominating.

5.1 Discussion of Major Sources

Wheel–Rail Contact The roughness of the rail and the wheel excite the wheel and rail, causing airborne and structure-borne noise. The structure-borne noise propagates to the car body through the bogie structure while the airborne noise from the wheels and the rails propagates around and along the vehicle. The source strength is proportional to the combined roughness,⁶ indicating that the combined roughness should be minimized. For well-maintained systems the rail controls the roughness at the longer wavelengths while the wheels dominate at the shorter wavelengths.

In addition to the combined roughness the source strength depends on a number of factors, such as wheel type, train speed, stiffness, and loss factor of rail pads and sleeper type, and can be calculated using prediction tools such as TWINS. The impact of train speed on the airborne source strength, L_v , is calculated as $30 \log(v/v_{\text{ref}})$ where v is the speed and v_{ref} is a reference speed.

The frequency content shifts somewhat toward higher frequencies at increasing speeds as the higher modes of the wheel will be excited. When predicting internal noise of suburban trains and trams, this effect is normally disregarded due to its limited influence.

Bogie Connections to Car Body In addition to the source strength of the wheel–rail contact, the structure-borne input to the car body is influenced by the bogie design and the flexibility of the resilient element used for connecting the various elements to the bogie frame and car body. At each connecting point between the bogie and car body, three translational and

three rotational components are present. A simplified approach is needed to enable a feasible description of the source strength that must also include the influence of multiple connections.

For engineering purposes the cross-coupling contributions are ignored, and a conservative estimation of the source strength per octave band is obtained by an energy summation of the maximum translational component independent of direction of the different connections in the octave band in question. The effect of train speed on the structure-borne source strength, L_v , is calculated using $25 \log(v/v_{\text{ref}})$.

Traction Motors Electrical traction motors are normally of the asynchronous type. There are two major noise generation mechanisms, a mechanical source due to bearing and magnetic forces and an aerodynamic source caused by the cooling air. For liquid-cooled motors this latter source is moved from the motor to the cooling unit.

Independent of motor cooling scheme, the mechanical noise dominates at lower speeds as the restricted switching frequency of the semiconductors controlling the motor speed and power results in a nonsinusoidal current being supplied to the motor. The motor torque fluctuates with frequencies related to the pulse pattern used.

The typical controlling scheme results in a torque that pulsates with a fixed frequency between approximately 600 and 800 Hz at low train speeds. At intermediate speeds the frequency of the pulsating torque changes with train speed, often in a quite complicated way, with a frequency span often between 600 and 1000 Hz. At higher train speeds a block-type pulse pattern is used, reducing the level of the pulsating torque.

This means the pure tone problems can be found at speeds up to 50% of maximum speed.

The presence of pulsation torque at low speeds aggravates the pure-tone problem as the masking from the broadband wheel–rail noise is missing. The magnitude of the pulsating torque in the motor air gap is considerable; a value corresponding to 30% of the nominal torque is quite normal creating a high structure-borne noise level at frequencies where structural resonance problems can hardly be avoided.

Some remedial actions are, however, at hand:

- The pulse frequencies can be changed to avoid a resonance condition.
- At lower train speeds with fixed pulse frequency, dynamic absorbers can be applied, thereby decreasing the mobility of the structure.
- Structural changes and use of soft resilient mountings, possibly combined with blocking masses, can reduce the transmission of structure-borne noise to the car body.

For self-ventilated motors the fan noise follows a 50 to 55 log speed dependence. The source strength is normally rather high, as the fan has to work for both driving directions, which means that a noisy radial straight blade design is applied. Absorption-type silencers have been used on traction motors to reduce airborne A-weighted noise levels by as much as 10 dB to 13 dB without reducing the airflow or causing a significant increase in motor temperature.

For vehicles with a single-floor construction both the airborne and structure-borne contribution from the motors has significant impact on the internal noise,

whereas structure-borne noise has the greatest impact where double-floor construction is used.

Cooling Units The noise from roof cooling units is a key element in the external noise. It is important to place such units away from openings connecting the outside of the vehicle to the interior, for example, the exhaust air openings for the HVAC system. Sufficient space, 50 to 100mm, should be left between the underside of the unit and the roof of the train to avoid coupling through the cavity. Proper balancing of the fans can reduce structure-borne noise problems.

Gearbox The main problem with gears is the structure-borne noise. The main transmission is normally through the torque reaction arm connected to the bogie frame. The transmission of structure-borne noise can be reduced by using soft rubber bushings (Shore A < 50°) in combination with a low mobility of the source and receiving structure. Due to lack of masking from other sources, natural frequencies of the supporting structure being excited by the tooth mesh forces at low to middle speed of the vehicles should be avoided. The source strength of gears follows a 25 log speed dependence and a 10 to 15 log power dependence.

Diesel Engines Diesel engines are particularly troublesome as both the airborne and structure-borne source strength is high. During both idling and acceleration, masking noise from other sources is absent. Consequently, a highly efficient mounting, most likely double elastic, is needed in combination with a high sound transmission loss of the car body structure adjacent to the engine. For roof-mounted engines, an enclosure closed toward the roof reduces the problems of airborne noise, provided adequate cavity height is observed. It is the experience of the author that, provided the Shore hardness is below 50°, a mounting system using rubber mounts can be very efficient. The source strength of diesel engines follows a 20 to 25 log speed dependence and a 4 to 6 log power dependence.

Traction Inverter and Transformers Besides noise from fans, which affect the external noise, the main problem here is pure-tone excitation (as discussed for the traction motor). A well-designed resilient mounting can minimize the contribution from this equipment.

Heating, Ventilation, and Air-Conditioning Units HVAC units are sources of both airborne and structure-borne noise. Structure-borne noise problems are more pronounced when using reciprocating piston-type compressors. The excitation originates from the unbalanced forces and moments of the compressor and from the pressure pulsations in the cooling circuit. When a reciprocating compressor is used, a well-designed resilient mounting of the complete unit can reduce the structure-borne noise sufficiently. With adequate space between the unit and the neighboring car body structure as described above, the remaining airborne noise

problem originates from the fresh air supply fan(s). For high air exchange rates the A-weighted sound power level of the fan can be up to 85 to 90 dB. The traditional solution is to introduce a baffle-type absorbing silencer between the fans and the first air outlets. An active solution has not yet been implemented in trains. The silencer can often have a length of 1 to 1.5 m, which indicates that the air duct concept has to take the silencer into account. Likewise the return air ducts should be designed with absorption in order to avoid break-out noise from the mixing chamber. Another problem of HVAC systems are the duct connections between the outside and interior of the train for fresh air intake and exhaust air outlet. It is necessary to ensure that these openings will not degrade the sound transmission loss of the train element in question. The aforementioned silencers will often help achieve the necessary sound transmission loss.

Hydraulic Equipment Hydraulic systems incorporating an engine-mounted pump and hydraulic motors for driving fans and generators are sometimes used on diesel and diesel/electric trains. The structure-borne source strength caused by pressure pulsations of these systems is very high, and severe pure-tone noise problems can be present. These systems should always be equipped with in-line silencers of the reactive type in order to reduce the level of the pressure pulsations. Furthermore, resilient mounting of the high-pressure pipes is necessary. Blocking masses are quite often necessary as the source mobility of the pipes is high.

Brake Resistors and High-Power Cables Brake resistors and high-power cables can be a source of structure-borne noise with the excitation mechanism due to magnetic forces and frequencies similar to those described for traction motors. Bundling of the cables minimizes the external field and can reduce the source strength. As the brake resistor structure normally is quite lightweight, a resilient mounting of the unit and/or use of blocking masses at the mounting positions can be helpful.

5.2 Typical Source Strength

Figure 1 shows typical source strengths of some of the sources discussed above. The levels stated are for low-noise equipment normalized to a train speed of 130 km/h. The structure-borne properties shown are the level at the interface to the car body.

6 PATH

6.1 Airborne Noise

Exterior Sound Field around Car The sound pressure level outside the car is attenuated as the distance to the sources increase due to geometrical spreading and diffraction. Figure 2 shows the calculated A-weighted sound pressure level at the outer surface of a typical car running in free field using a typical source spectrum

Sound Transmission Loss of Car Body and Elements The highest sound pressure level is normally found under the train adjacent to the bogies,

Figure 1 Typical source strengths at 130 km/h.

Figure 2 A-weighted sound pressure level around the car body.

indicating a need for a high sound transmission loss. Because of the desirable low mass design, a double construction is required. The double-wall resonance frequency should be as low as possible (50 to 100 Hz), which means the cavity height should be a minimum of 50 to 60 mm to match the surface mass of typical floor constructions. Car bodies made of extruded aluminum profiles present a special problem, as the sound transmission loss of the double-wall profiles is lower than expected per the mass law in the middle-frequency range. The low sound transmission loss is caused by an acoustical unfavorable mass/bending stiffness ratio resulting in a low coincidence frequency. A sufficient cavity height is therefore particularly important. The cavity should be completely filled with highly efficient absorption material such as mineral wool or fiberglass in order to achieve the maximum sound transmission loss in the middle- to high-frequency range.

Rigid connections between the inner floor and the car body will reduce the sound transmission loss above the double-wall resonance. A floating floor, that is,

resilient support of the upper floor, can result in 5 to 15 dB higher sound transmission loss. The resilient supports can be either point supports or line supports. The line support principle can offer better results, as the local mobility differences are greater than what can be achieved with point supports.

Sandwich panels are becoming increasingly popular as this construction offers low mass and high bending stiffness. If a foam-type core material with a fairly low shear modulus (<20 MPa) is used, a favorable combination of high static stiffness and a sound transmission loss similar to a single panel of the same mass can be obtained.⁷

Double-glazing windows should be asymmetric, and double lip seals should be used for doors.

Typical Sound Transmissions Losses Examples of sound transmissions losses for constructions used in trains are shown in Table 3.

Figure 3 shows the sound transmission loss plotted against octave band center frequency for some typical floor constructions.

6.2 Structure-Borne Noise

Receiver Properties Reducing the mobility of the mounting position on the car body especially when a resilient element is present between the source and receiver can reduce the transmission of structure-borne noise to the car body. A reasonable target for the mobility level, in the frequency range of 30 to 1600 Hz, is -100 to -90 dB re 1 m/Ns for underfloor-mounted equipment and -90 to -80 dB for roof-mounted equipment. The expected mobility levels can be calculated using FEM.

Damping of the Car Body Traditional sprayable damping compounds in 3 to 5 mm thickness are used to increase the mechanical losses of steel car bodies. This measure has also been applied to aluminum car bodies, but due to the much higher bending stiffness

the damping is only efficient above 400 to 500 Hz, that is, above the frequency range where the structure-borne noise normally has an influence.

In cases where space restrictions hinder the use of floating floors, an improvement of the structure-borne noise properties can be achieved by applying constrained layer damping to the car body structure at the point of excitation and the surrounding area. Normal floor plates of plywood have sufficient bending stiffness to work as the constraining layer.

Typical Propagation Losses For a rough estimation, the typical structure-borne propagation losses in the range of 63 to 500 Hz are of the order of 5 dB/m in the vertical direction and 1 to 3 dB/m in the lengthwise direction. The actual losses will depend on the specifics

of the car body structure and can be determined using SEA calculations combined with measurements.

Typical Structure-Borne Sound Transmission Losses and Radiation Ratios The structure-borne sound transmission loss, TL_v , describes the difference between the vibration level on the outer skin of the car body and the vibration level on the interior surface. Resilient mounting of the inner panel as used for, for example, floating floors increases the structure-borne transmission loss. Resilient mounting of lightweight panels on a significantly heavier structure such as the car body side should be used with caution to avoid the risk of increased vibration levels on the inner panel.

The TL_v of, for example floating floors is controlled partly by the transmission through the resilient supports and partly by airborne excitation via the cavity.⁸ This means that the properties of the resilient support are less critical with a small cavity height and vice versa.

Measured radiation ratios are considerably higher than those found by the classical Maidanik method.⁹ Since the majority of the surfaces radiating structure-borne noise to the interior are part of a double construction, the radiation ratio differs probably because of the forced wave excitation from the acoustical field in the cavity.

7 RECEIVER

The receiver is the passenger area or the driver's cab. Besides using internal doors to separate noisy areas such as entrances and gangways from the rest of the passenger area, it is very beneficial to maximize the amount of absorption. Increasing the absorption decreases the sound pressure level and the reverberation time and improves the privacy and RASTI figures. Absorption can also help reduce standing-wave problems. Cushion seats with cloth cover can provide large absorption areas if the specific flow resistance of the

cloth is of the order of 1 to 3 times $\rho_{\text{air}}c$, and the cushion material has good absorption properties. Materials with these properties that also meet strict fire requirements are available. The ceiling can also provide a high absorption area when the specific flow resistance is approximately 2 times $\rho_{\text{air}}c$. This can be achieved with a thin permeable sheet, thus avoiding any risk of contamination by fibers.

8 VALIDATION

The acoustical model of the vehicle will be based on a number of assumptions and simplifications. To validate the acoustical model before the train is running on the track, a number of measurements should be carried out. Performing these validation measurements allows for corrective action at as early a stage as possible.

1. One must verify that the equipment has met specifications.
2. One must verify that the car body elements have the calculated properties.
3. One must verify that the complete car has the modeled properties.

Testing of equipment follows relevant International Organization for Standardization (ISO) standards and procedures as defined in the equipment specifications. Testing of important car body elements, such as floor, sidewall, windows, and intercommunication gangways should follow ISO 140 procedures. The sample size for floors can be as little as 1.5 m² for initial investigations. For final measurements the sample size should follow the ISO recommendation, that is, 10 m² in order to obtain reliably low frequency results. The measurement results shall include the airborne sound transmission loss, the radiation ratio, and the structure-borne sound transmission loss. For testing of the airborne noise properties of the car, the interior of the car is used as sending room and the transmitted sound power through the element under investigation is measured using intensity. Practical experience shows that shielding of the other surfaces improves the accuracy of the measurement. The structure-borne properties are investigated using an electrodynamic shaker as source while the radiated noise to the interior of the car is measured using the intensity technique. Again shielding improves the accuracy. This method can also be used to measure the global pressure/force or pressure/velocity transfer function. However, this method is rather time consuming if you need the transmission properties from several connection points in three directions. Using a type 1 reciprocity technique¹⁰ the pressure/velocity transfer function can be readily determined for all connections and directions by

measuring the free velocity at the uncoupled connection points when exciting the interior with an omnidirectional sound source of known volume velocity strength.

9 VERIFICATION

Testing methods and procedures for commissioning measurements are defined in ISO 3381 for internal noise.¹¹ This standard has recently been revised. The revised standard offers more well-defined test conditions, enabling repeatable and comparable results. The revised standard prescribes that the surface roughness of the rails at the test site must be measured and under a certain limit.

1 INTRODUCTION

Off-road vehicles are self-propelled machines used largely for infrastructure development and maintenance or agricultural applications. Common uses for such vehicles include earth moving, automobile and railway construction, communication networks, airport and building construction, various kinds of repair and maintenance, and farming. Modern off-road vehicles can be self-contained vehicles or machines attached to tracked or wheeled industrial tractors. The following are some of the uses of these off-road vehicles: (1) preparation of agricultural or building sites, (2) earth moving, (3) road laying, and (4) as cranes. Common machine types that perform these functions include tractors, tracked bulldozers, graders, loaders, cranes, vibratory compactors, excavators, and other types of track/crawler or wheeled vehicles.

Most off-road machines are equipped with cabs that provide safety and comfort for operators. The A-weighted sound pressure levels inside cabs during machine operation are usually in the range of 65 to 85 dB. The interior noise level depends on a number of factors. Among the most significant factors are the operation of the machine and various vibroacoustical properties such as the efficiency of the cab vibration isolation, cab wall sound transmission loss, structural damping, interior sound absorption, and the features and locations of the dominant noise sources. Interior noise reduction is effective if two main problems are solved: first, if the dominant noise source and path contributions to the cab noise are well understood and, second, if optimal noise reduction methods are used.

2 TYPICAL CONSTRUCTION DETAILS AND MAIN NOISE SOURCES OF OFF-ROAD VEHICLES

Off-road vehicles are usually powered by a diesel internal combustion engine (ICE) coupled with a mechanical drive. The internal combustion engine may be located within a hooded enclosure (Figs.1a–d) or in a diesel compartment (Fig.1e). Some off-road vehicles

such as cranes may have an electrical drive, where the diesel engine powers an electric generator that in turn powers the machine implement. Most off-road vehicles (graders, loaders, excavators, tracked dozers, etc.) are equipped with specific attachments (buckets, blades, etc.) that, as a rule, do not emit significant noise during operation cycles. The primary noise sources for such machines are typically the ICE body (mechanical noise source), the exhaust, and intake of the ICE (air dynamical noise sources). The internal combustion engine cooling system fan is an aerodynamic noise source in off-road machines, and transmission elements are mechanical noise sources. Hydraulics pumps and lines are fluid-borne or fluid-structural noise sources. If a vehicle attachment is characterized by significant emission of noise and vibration (such as a vibratory compactor), these attachments usually become the dominant noise source. In general, a track undercarriage is a dominant noise source of a tracked off-road vehicle during dynamic operating cycles.

The shock interaction of two or more objects, friction of interacting surfaces, aerodynamic turbulence of airflows, forced oscillations of solid bodies, influence of variable magnetic forces, and pressure pulsations in hydraulic systems may each be significant contributors to cab noise. Considering the causes and characteristics, noise sources in off-road vehicles may be divided into the four following classes: mechanical, aerodynamic, hydraulic, and electromagnetic.

Table 1 contains typical sound power level spectra of primary noise sources of off-road vehicles.¹ It is shown that noise emitted by the ICE exhaust and intake systems is characterized by distinct low-frequency components; noise emitted by the ICE body has high-frequency characteristics, and the other noise sources have mid- to high-frequency characteristics. Table 1 also presents A-weighted sound power levels varying from 85 dB to 105 dB for several types of off-road machines. It is shown that the ICE body and vibrating attachments are the noisiest sources, while the ICE intake is the quietest source for most types of off-road machines.

Figure 1 Examples of off-road vehicles: (a) excavator, (b) tracked dozer, (c) loader, (d) vibratory compactor, and (e) crane (engine compartment type): (1) machine attachment (bucket, dozer, crane boom, etc.), (2) cab, (3) internal combustion engine, (4) ICE exhaust pipe, (5) ICE intake, (6) muffler, (7) ICE enclosure, (8) vibration active attachment (vibrating roller), and (9) diesel compartment.

Table 1 Average Sound Power Level Spectra of Typical Noise Sources of Off-Road Vehicles

No.	Type of Noise Source	Sound Power Levels (dB) in Octave Frequency Bands (Hz)								A-weighted Sound Power Level (dB)
		63	125	250	500	1000	2000	4000	8000	
1	ICE body	90	100	96	98	100	100	98	95	105
2	ICE exhaust system (with presence of a muffler)	95	105	100	90	90	87	85	80	95
3	ICE intake	82	92	86	80	80	80	75	73	85
4	ICE cooling fan	85	95	100	97	95	92	87	82	100
5	Vibrating roller	100	102	96	104	101	90	83	72	105
6	Track	75	78	85	83	82	85	78	69	90
7	Hydraulic pump	78	80	86	92	92	85	80	76	95

3 OFF-ROAD VEHICLE INTERIOR NOISE MEASUREMENT PROCEDURE

Two international standards are most often employed to measure noise at the operator station for a large majority of off-highway vehicles.^{2,3} Other standards for measuring operator noise have been developed for specific machine types (e.g., agricultural machines), but their approach is similar to the procedures in Refs. 2 and 3.

The operator is in the driving position during measurements. The microphone is oriented horizontally, pointing in the direction in which a person occupying the operator's seat would normally look. The microphone is located 200 ± 20 mm from the medium plane to the side of the operator's head where the time-averaged A-weighted sound pressure level is highest.

Measurements can be made for stationary and dynamic conditions. The time-averaged A-weighted sound pressure level, in decibels, is determined either by using Eq. (1) or by using digital integration sound level meters:

$$L_{p_{Aeq}T} = 10 \log \left[\frac{1}{T} \int_0^T \frac{p_A^2(t)}{p_0^2(t)} dt \right] \text{ dB} \quad (1)$$

where T = measurement period

$p_A(t)$ = instantaneous A-weighted sound pressure of the sound signal, Pa

$p_0(t)$ = reference sound pressure
($p_0 = 2 \times 10^{-5}$ Pa)

Measurements are taken with the doors and windows closed and the ventilating system(s) running. The minimum number of measurements at each microphone position is three. It is necessary to have two of the readings be within 1 dB of each other. If this condition is not satisfied, additional readings are taken to meet the requirement. The reported value of the time-averaged A-weighted sound pressure level will be the arithmetic mean of the two highest values that are within a 1-dB range of each other.

Other measurement techniques (e.g., sound intensity) are also suitable for scientific and detailed studies of these kinds of vehicles.⁴⁻⁶

4 OFF-ROAD INTERIOR NOISE LIMITS

Off-road interior noise limits are settled by each country considering domestic legislation and may have obligatory or recommendation status. Table 2 contains permissible levels at operator position of off-road vehicles accepted by several countries.

At the same time, low interior noise as well as sound quality can play a significant role in product differentiation and commercial success. Thus, interior noise levels are being driven lower by market pressures and competition.

5 INTERIOR NOISE CHARACTERISTICS

Characteristic spectra of interior noise of two off-road vehicles are presented in the Fig. 2. Experimental investigations show that off-road vehicle interior noise is characterized by dominant contributions of low-frequency

Table 2 Off-Road Interior Noise Level Limits

Country	Interior A-weighted Sound Pressure Level Limit (dB)
United States	85
Japan	73
European Union countries	85
Russia	80

components. In contrast, the major contributions to exterior noise (e.g., noise emitted by the ICE body, vibrating roller, etc.) are characterized by higher frequency content.^{1,7} This suggests that cabs of off-road machines, as a rule, have relatively high sound isolation.

All off-road vehicles may be conventionally divided onto three groups considering dominant interior noise contributions:

Group I is characterized by dominant noise emitted by the ICE.

Group II is characterized by dominant noise emitted by vibration-active attachment and lower contribution emitted by internal combustion engine.

Group III is characterized by similar noise contributions emitted by the ICE and by an undercarriage drive.

Average interior levels of wheel and tracked off-road vehicles and vibratory compactors with enclosures adjoined to cabs are presented in the Table 3.

Separating the vehicle cab from the engine compartment by an air gap can yield additional A-weighted sound pressure level reduction of 3 to 5 dB. Interior noise in wheel and tracked vehicles in static conditions is 1 to 3 dB lower than in dynamic conditions and is in the range of 70 to 75 dB. A vibratory compactor's interior A-weighted sound pressure level measured during dynamic conditions is about 10 dB higher than static conditions and is dominated by the ICE and the vibrating roller drum.

Interior noise depends significantly on the operating conditions. Reducing the engine speed is one way to provide lower noise emissions of off-road vehicles.

Figure 2 Average characteristic sound pressure level spectrum of interior noise in some off-road vehicles for specific conditions of work: (1) vehicles without vibration active attachments (e.g., excavators, loaders, tracked dozers, graders) and (2) vehicles with vibration active attachments (e.g., vibratory compactor).

Table 3 Interior Noise in Diesel-Powered Off-Road Vehicles During Typical Operating Conditions

Vehicle Group	Vehicle Type	Interior A-weighted Sound Pressure Levels for Various Work Conditions (dB)	
		Stationary Condition	Dynamic Condition
I	Wheel excavators, loaders, graders	70–75	71–77
II	Self-propelled vibratory compactors	73–76	80–86
III	Tracked dozers	70–75	72–78

Such measures may reduce the interior A-weighted sound pressure level by 2 dB to 3 dB.

Interior noise levels also depend on the year of vehicle production. Around 25 to 30 years ago the interior A-weighted sound pressure level in most off-road vehicles was about 90 dB to 95 dB.

6 PREDICTION OF AIRBORNE NOISE IN CABS

An example of predicting airborne sound contribution in a tracked dozer cab is presented below. The calculation scheme of the noise generation processes inside a tracked dozer cab is shown in Fig. 3. The following noise sources are considered in the calculation scheme: the ICE body located in engine compartment, exhaust and intake pipes located outside and above the enclosure, and the crawler undercarriage.

There are several dominant noise propagation paths into the cab: from the engine compartment through the partition, through the enclosure panels, and then through the cab elements (excluding the cab floor and the partition), from the exhaust stack and intake port through cab elements, through the undercarriage, and then through the cab floor and other panels.

Sound pressure levels are predicted in octave bands, and the A-weighted sound pressure level is estimated using the A-weighting filter correction of a sound level meter.

The primary assumptions of the prediction method include the following statements¹: The sound field in the cab is quasi-diffuse, the sound sources are incoherent, and the sound pressure at the receiving point is determined by the energy summation principle. The cutoff frequency (frequency where the field is regarded as quasi-diffuse) for the aforementioned

assumptions is estimated by Eq. (2):

$$f_{\text{dif}} = \frac{200}{\sqrt[3]{V}} \text{ Hz} \quad (2)$$

where V is the cab volume (in m^3).

An analytical description of the primary noise source contributions into the off-road vehicle interior sound field is presented below. The noise contribution from the diesel engine that propagates into the cab through the partition, located between the engine compartment and the cab (e.g., a firewall), is determined by the Eq. (3):

$$L_{\text{eng_part}}^{\text{int}} = L_W^{\text{enc}} + 10 \log \left(\frac{\chi_{\text{enc}}}{S_{\text{enc_total}}} + \frac{4\psi_{\text{enc}}}{B_{\text{enc}}} \right) + 10 \log \frac{S_{\text{part}}}{\sum_{i=1}^n S_{\text{enc}_i}} - \bar{S}_{\text{Ipart}} - 10 \log A_{\text{cab}} + 6 \text{ dB} \quad (3)$$

where L_W^{enc} = total sound power emitted within the enclosure, dB

χ_{enc} = coefficient of the effect of the near sound field of the enclosure (Fig. 4)¹

ψ_{enc} = coefficient of the sound field diffusivity violation under the enclosure (Fig. 5)¹

$S_{\text{enc_total}}$ = total area of the enclosure panels, m^2

B_{enc} = enclosure constant, m^2 , which is estimated as follows:

Figure 3 Scheme of main noise contributions considered in the prediction model of the airborne noise emitted by a tracked dozer: (1) crawler undercarriage, (2) enclosure, (3) intake, (4) engine, (5) exhaust, (6) cab, (7) partition, and (8) engine compartment.

Figure 4 Diagram of the χ -coefficient estimation depending on the ratio of the distance R and the maximum linear dimension of the noise source l_{max} .

Figure 5 Dependence of the coefficient ψ of the sound field diffusivity violation in a closed room on the ratio of the room constant (A_r) to the room area (S_r).

$$B_{\text{enc}} = \frac{A_{\text{enc}}}{1 - \bar{\alpha}_{\text{enc}}}$$

where A_{enc} = equivalent enclosure sound absorption, m^2 , estimated by the following equation: $A_{\text{enc}} = \bar{\alpha}_{\text{enc}} S_{\text{enc_total}}$

$\bar{\alpha}_{\text{enc}}$ = average coefficient of sound absorption of the enclosure

$\sum_{i=1}^n S_{\text{enc}_i}$ = area of the enclosure panels, where sound propagates into the environment, m^2

S_{enc_i} = area of the i th panel of the engine enclosure where sound propagates into the environment, m^2

n = number of panels where sound propagates into the environment

$\bar{S}\bar{I}_{\text{part}}$ = average sound isolation of the partition, dB

S_{part} = area of the partition located between the diesel compartment and the cab, m^2

A_{cab} = equivalent cab sound absorption, m^2 , estimated by the following equation:

$$A_{\text{cab}} = \bar{\alpha}_{\text{cab}} S_{\text{cab}}$$

$\bar{\alpha}_{\text{cab}}$ = average coefficient of sound absorption of the cab

S_{cab} = total area of cab shielding elements (glass, floor, walls, ceiling, etc.), m^2

Measured sound absorption coefficients of cabs and enclosures are presented in the Table 4. Magnitudes of $L_{W_{\text{exh}}}^{\text{enc}}$ and $\bar{S}\bar{I}_{\text{part}}$ may be determined by theoretical predictions or from experiments.^{1,7}

The exhaust contribution to the interior noise is estimated by the Eq. (4):

$$L_{\text{exh}}^{\text{int}} = L_{W_{\text{exh}}} - 20 \log \frac{R_{\text{exh}}}{r} - 10 \log \frac{\sum_{i=1}^m S_{\text{cab}_i}}{\sum_{i=1}^m S_{\text{cab}_i} \times 10^{-0.1(\bar{S}\bar{I}_{\text{cab}_i} + t_{\text{dif}_i}^{\text{cab}})}} + 10 \log \frac{\sum_{i=1}^m S_{\text{cab}_i}}{A_{\text{cab}}} + \text{DI}_{\text{exh}} - x + 6 \quad (4)$$

where $L_{W_{\text{exh}}}$ = sound power level generated by the exhaust (to be predicted or measured), dB

R_{exh} = distance between the exhaust pipe end and the nearest panel of the cab, m

r = distance from the exhaust pipe end to the microphone position where exhaust noise was measured, m

S_{cab_i} = area of the i th cab panel through which noise penetrates into the cab, m^2

n = number of cab panels where sound penetrates into the cab

$\bar{S}\bar{I}_{\text{cab}_i}$ = i th cab panel sound isolation, dB

$t_{\text{dif}_i}^{\text{cab}}$ = i th cab panel sound isolation

correction (depends on location of the panel relatively the exhaust pipe), dB, $t_{\text{dif}_i}^{\text{cab}} = 5$ dB for the ceiling and the side panels of the cab, $t_{\text{dif}_i}^{\text{cab}} = 8$ dB for the back panel

DI_{exh} = exhaust directivity index, dB

x = radiation correction, which depends on the spatial angle of sound radiation, $x = 10 \log \Omega$, where Ω is the noise source spatial angle of sound radiation, in other words, $x = 5$ dB, for $\Omega = \pi$ ("1/4 space" radiation), $x = 8$ dB, for $\Omega = 2\pi$ ("half-space" radiation), $x = 11$ dB, for $\Omega = 4\pi$ ("full-space" radiation)

A_{cab} = as already defined in Eq. (3)

Table 4 Magnitudes of Average Coefficients of Sound Absorption of Close Volumes

Descriptor	Octave Frequency Bands Magnitudes of Average Sound Absorption Coefficients							
	63	125	250	500	1000	2000	4000	8000
α_{cab}	0,09	0,15	0,18	0,25	0,25	0,25	0,25	0,28
α_{enc}	0,08	0,12	0,16	0,2	0,26	0,3	0,3	0,35

The undercarriage contribution to the interior sound field of an off-road vehicle propagating through a cab floor is determined by the Eq. (5):

$$L_{\text{undercar_floor}}^{\text{int}} = L_{W_{\text{undercar}}} - 10 \log \frac{R_{\text{undercar}}}{r} - \overline{SI}_{\text{floor}} + 10 \log \frac{S_{\text{floor}}}{A_{\text{cab}}} + 1 \quad \text{dB} \quad (5)$$

where $L_{W_{\text{undercar}}}$ = sound power emitted by the undercarriage, dB

R_{undercar} = average distance from the undercarriage to the floor

$\overline{SI}_{\text{floor}}$ = average sound isolation of the floor
 r = distance where undercarriage noise is measured, m, ($r = 1$ m)

S_{floor} = floor area, m²

Other contributions, such as intake noise ($L_{\text{int_pipe}}^{\text{int}}$), noise propagating through the enclosure underneath opening considering ground reflection ($L_{\text{open}}^{\text{int}}$), undercarriage noise propagating through the cab walls ($L_{\text{undercar_walls}}^{\text{int}}$), and noise emitted by the engine that is transmitted through the enclosure and cab panels ($L_{\text{eng_encl}}^{\text{int}}$) are each determined in a manner similar to the components already considered. The total spectrum of the off-road interior noise is estimated by Eq. (6):

$$L_{\text{airborne}}^{\text{int}} = 10 \log (10^{0.1 L_{\text{int_pipe}}^{\text{int}}} + 10^{0.1 L_{\text{open}}^{\text{int}}} + 10^{0.1 L_{\text{eng_enc}}^{\text{int}}} + 10^{0.1 L_{\text{eng_part}}^{\text{int}}} + 10^{0.1 L_{\text{undercar_floor}}^{\text{int}}} + 10^{0.1 L_{\text{undercar_walls}}^{\text{int}}} + 10^{0.1 L_{\text{exh}}^{\text{int}}}) \quad \text{dB} \quad (6)$$

Examples of interior noise in a tracked dozer cab is presented in Figs. 6 and 7. It follows from analysis of Fig. 7 that the dominant noise components propagate into the cab by the first and second pathways (from engine compartment through the partition between the cab and diesel compartment and from engine compartment through the enclosure underneath opening). This suggests that the most effective noise reduction would be achieved by increasing the sound isolation of the partition and from decreasing the opening underneath the enclosure. The next step would be to enhance the ICE exhaust muffler's efficiency. The predicted results also help determine the magnitude of the required noise reduction level for each component to achieve certain interior sound field goals.

This prediction method allows one to solve at least two important tasks:

- Theoretically predict interior sound field parameters of an off-road vehicle at the design stage
- Separate noise source contributions into interior sound field for already produced vehicle

Figure 6 Example of theoretically predicted interior noise spectrum of a tracked dozer: (1) exhaust noise contribution, (2) intake noise contribution, (3) diesel noise contribution propagating through the partition between the engine compartment and the cab, (4) diesel noise propagating through enclosure underneath opening, (5) diesel compartment noise propagating through the enclosure panels, (6) undercarriage noise contribution propagating through the cab panels, (7) undercarriage noise contribution propagating through the cab floor, and (8) total airborne interior sound field of a tracked dozer.

Figure 7 Example of predicted separate A-weighted sound pressure levels emitted by a tracked dozer noise sources propagating into a cab by the following paths: (1) from diesel compartment through the partition between the cab and diesel compartment, (2) from diesel compartment through the enclosure underneath opening, (3) from exhaust, (4) from the undercarriage through the cab floor, (5) from the diesel compartment through the enclosure panels, (6) from the undercarriage through the cab panels (except cab floor), (7) from intake, and (8) total airborne interior sound field.

7 DETERMINATION OF STRUCTURE-BORNE SOUND CONTRIBUTION

The internal combustion engine (ICE) and attachments with intrinsic vibration or shock emissions are the main sources of structure-borne sound in off-road vehicles. Vibration is transmitted through the base of the vibration source onto the vehicle frame and then propagates through the cab base to shielding elements of the cab. Vibration attenuation may be

achieved in bearing junctions if vibration isolation is used. Vibration also may be reduced during vibration transmission through the frame or shielding elements of the cab. Separation of structure-borne and airborne sound is an important step of interior noise reduction. Structure-borne sound in the cab may be separated from the airborne sound by means of analytical or numerical methods.^{8,9}

Finite element method (FEM) is one of most widely used numerical methods for prediction of interior structure-borne sound. Vibration velocity levels emitted by cab surfaces are initial input data for FEM prediction. Cab elements such as the air volume, rubber seals for cab windows, and hard edges are represented by sets of elements. An FEM model of a cab is presented in Fig. 8. Various commercial software tools for FEM analysis are available. FEM has several significant restrictions, which often result in it being applied only to the low-frequency range (up to 200 to 250 Hz) for typical cab models. Estimation is carried out per particular fixed frequencies while interior noise characteristics are often determined in octave frequency bands. Results of structure-borne sound prediction in a cab of a vibratory compactor and their comparison with experimental data are represented in Fig. 9.

Until recently, most components in off-road vehicles were hard mounted to frames or to each other. For recent designs, it may be stated that structure-borne sound reduction in most modern off-road vehicles (graders, excavators, loaders, etc.) has not been as critical as airborne reduction. This is because effective means of vibration isolation for internal combustion engines and cabs and effective vibration damping materials (with high loss factor) have become widely used in these vehicles, replacing older hard-mount junctions.

Contributions from structure-borne sound is comparable to airborne sound contribution in cabs only in the low-frequency range (usually 31.5 to 63 Hz), or in other words near the natural frequency of the internal combustion engine crankshaft (most internal combustion engines speeds are in the range of 1500 to 3000 rpm, or in other words, 25 to 50 Hz).

Figure 8 FEM model of a cab.

Structure-borne sound contribution is more significant for vehicles with an active attachment. In this case dominant vibration is found at frequencies close to a natural frequency of the vibrating attachment but some structure-borne contribution in higher frequencies (up to 200 to 250 Hz) is also considered.

For higher frequency analysis, beyond the typical frequency range of finite element analysis (FEA), statistical energy analysis (SEA) is often used to model off-road vehicle cabs. Instead of discretizing the cab geometry into small elements as with FEA, the SEA approach assumes the cab parts are larger, primitive structures such as plates, cylinders, beams, and acoustical volumes. SEA is used for both structure-borne and airborne situations. A simple cab model is shown in Fig 10.

Figure 9 Sound pressure levels inside a vibratory compactor cab for a condition when vibrating roll is active: (1) predicted results and (2) experimental data.

Figure 10 Simple SEA model of a cab. In this model the front window, door, and floor are single plate elements, which represent the flexural wave fields excited but an external pressure field.

Figure 11 Example results showing comparison of sound pressure level between SEA and measurement.

Figure 11 compares predicted spectrum from a SEA cab model compared to measured spectra from two identical machines. The solid line is the model prediction and the two dashed lines are from two different machines of the same type. This spectrum

is the sound level as predicted and measured in a cab of construction machine running at static, high idle.

Statistical energy analysis does not yield exact, deterministic results such as FEA. Rather, it produces spatially averaged, and band-averaged results. Run

times for a typical cab SEA model are on the order of 1 or 2 min, as opposed to hours for typical FEA models. Because SEA models work well for high-frequency prediction, they are a convenient tool for assessing acoustical trim options, such as materials for headliners or optimal thickness of a floormat decoupler. Also, because SEA models are typically less costly to build and validate than FEA models, SEA is often used to assess design trade-offs in the early concept phase before the design is too constrained.

8 NOISE REDUCTION IN CABS

8.1 Classification of Interior Noise Reduction Methods and Means

All interior noise reduction methods and means may be divided onto three main groups considering the following features: source of noise excitation; transmissibility; and response.^{1,9–11}

Source of excitation: Reducing the intensity of the exterior sound fields around a cab and decreasing the sound field emitted by noise sources inside a cab is accomplished by reducing the noise sources, by increasing of a distance between the cab and the noise source, by applying local baffles between the noise source and a cab, by installing mufflers, and by other means to lessen the source strengths or path contributions to the cab interior field.

Transmissibility: Structure-borne sound reduction is obtained by vibration isolation of a cab and/or the vibration source, by increasing the loss factor of cab elements emitting structure-borne sound, and by increasing of loss factor of vehicle frame constructions.

Response: Sound isolation of cab elements, sound absorption of inner cab volume, and acoustical tightness of a cab (preventing sound propagation through elements with lower sound isolation, openings, other leaks) are the main acoustical characteristics of a cab. Acoustical tightness of a cab may be improved with the use of baffles, tightening, and sealing of nonclosed elements, openings, and apertures. In particular, careful attention must be made to any penetrations into the cab (e.g., electrical wirings, hoses, linkages, brake lines, etc.) and any cab elements that open and shut (doors, windows). If a cab is not well sealed the effects of other noise control measures may be compromised.

A detailed classification of interior noise reduction methods is presented in Fig.12.

8.2 Sound Isolation and Sound Absorption

One-layer, two- or three-layer, and multilayer structures are used for sound isolation of off-road vehicles. Most simple examples of a one-layer cab shielding elements are glass panels. If other conditions are not changed sound isolation increases when surface mass is increased and when number of layers is increased.

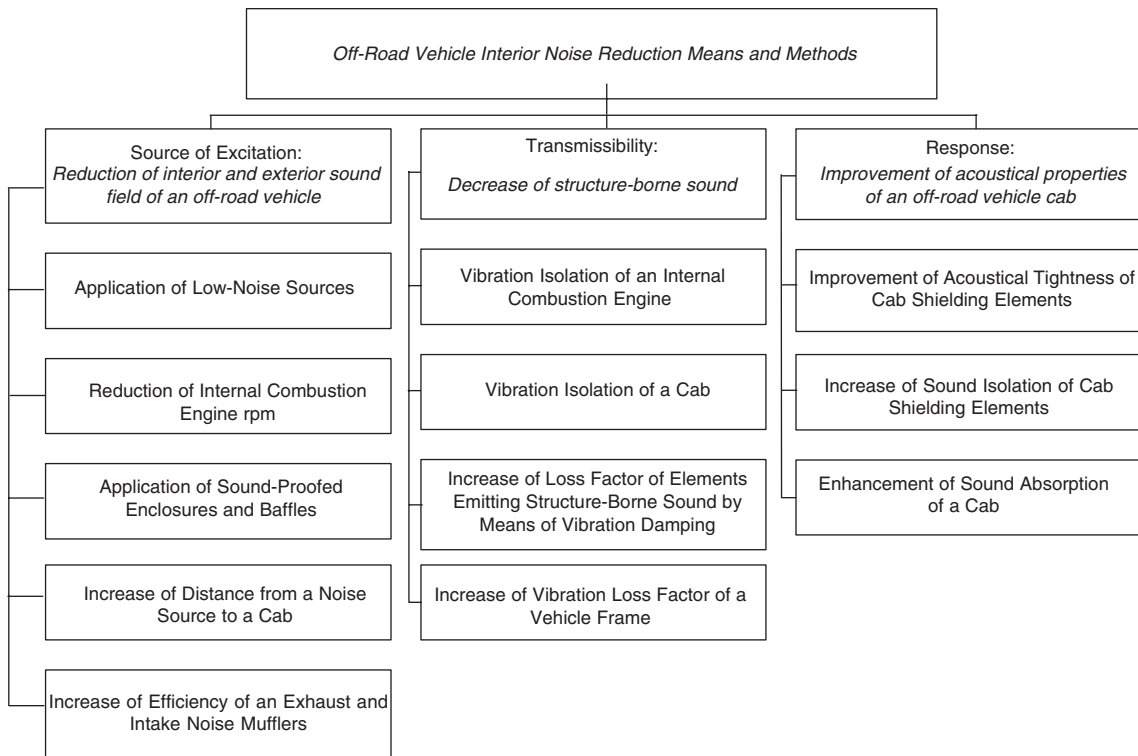

Figure 12 Classification of off-road vehicle interior noise reduction means and methods.

Figure 13 Examples of multilayer structures used for off-road cab shielding: (a, b) cab wall, (c) partition, (d, e) cab floor, (1) steel sheet, (2) soft sound absorptive porous material, (3) soft material (e.g. perforated vinilite), (4) damping coating, (5) fibred sound absorption material, (6) finishing material, (7) foam plastic, (8) rubber, and (9) intermediate air gap.

The last phenomenon is due to sound transmission through layers characterized by different impedance. It is well known that resonance phenomena in one-layer structures significantly decrease sound isolation. Application of multilayer structures increases sound isolation of a shielding element and may influence sound absorption and damping of a structure if some layers have good sound absorption or provide reliable vibration damping.

High sound isolation is found in three-layer structures with an intermediate connecting layer. Some examples of sound-proofed multilayer elements of off-road vehicles are presented in the Fig. 13. Table 5 contains average magnitudes of sound isolation of shielding elements of an off-road vehicle cab obtained from experiments.¹

Usually shielding elements of an off-road vehicle cab have rather high sound isolation of about 25 to 40 dB in the frequency range of 500 to 8000 Hz. At the same time sound isolation of cab floor in the medium and high-frequency range is by 10 to 15 dB lower than sound isolation of other metal panels at a particular frequency. This may be explained by insufficient acoustical tightness of a cab floor or the presence of some flanking path. The data shown in Figs. 6 and 7 show that the dominant noise contributions propagate into the cab through a partition located between the diesel compartment and the cab. Thus, increasing the sound isolation of this partition is the next step toward more effective interior noise reduction.

The average sound absorption coefficient ($\bar{\alpha}_{cab}$) is a characteristic of sound absorptive properties of a cab. Higher $\bar{\alpha}_{cab}$ yields lower reflected sound energy and

consequently lower interior noise. Sound absorption in a cab is obtained by adding sound absorptive materials, usually in the form of soft porous materials that are located at the cab ceiling (headliner) and on side or rear cab panels. The average sound absorption coefficient depends not only on the acoustical treatment of cab panels but also on sound absorptive characteristics of the driver seat and driver's clothing. An example of an average sound absorption coefficient spectrum from an off-road vehicle cab is represented in the Table 4. The values reach 0.1 to 0.2 in the low-frequency range and 0.2 to 0.3 in the medium and high frequencies. This means that some potential for further interior noise reduction of the A-weighted sound pressure level (by 1 dB to 1.5 dB) exists and may be obtained by using acoustical treatment with sound absorption in the medium- and high-frequency range of 0.35 to 0.45. Further increasing the average sound absorption of a cab is almost impossible for most off-road vehicles due to construction features of an off-road vehicle cab (e.g., most cabs have a high percentage of glass).

8.3 Vibration Isolation and Vibration Damping

Double vibration isolation is widely used in off-road vehicles. Vibration isolators are mounted under the internal combustion engine and under the cab, as a rule. Combined vibration isolators made from rubber and metal are used (Fig. 14).

Vibration isolation efficiency is determined by the value of the static displacement of a vibration-isolated object located on vibration isolators and by correlation of the frequency of forced oscillations (f_f) and the natural frequency (f_n). Higher static displacement provides more significant effect on vibration isolation. The vibration effect (VE) for low-frequency range

Figure 14 Examples of vibration isolators of off-road vehicle cabs: (1) cab bracket, (2) main rubber element, (3) bracket, (4) additional rubber element, (5) fixing element, and (6) fastening bolt.

Table 5 Average Magnitudes of Sound Isolation of Shielding Elements of an Off-Road Vehicle Cab

Type of Shielding Element of a Cab	Sound Isolation (dB) in Octave Frequency Bands (Hz)							
	63	125	250	500	1000	2000	4000	8000
One-layer glass	13	18	25	28	32	29	32	38
Multilayer metal element	18	23	27	31	35	33	36	40
Three-layer partition between diesel compartment and a cab	15	21	24	26	27	30	30	35
Multilayer floor	14	18	21	21	20	23	26	30

of $(2 \div 5) \frac{f_f}{f_n}$ may be estimated by the following equation:

$$VE = 40 \log \frac{f_f}{f_n} \text{ dB} \quad (7)$$

where f_f is the frequency of forced oscillations.

The frequency of forced oscillations of an internal combustion engine crankshaft may be determined by Eq. (8):

$$f_f = \frac{n}{60} \text{ Hz} \quad (8)$$

where n is number of cycles, in revolutions/minute (rpm).

The natural frequency of a vibration-isolated object depends on the static displacement by Eq. (9):

$$f_n = \frac{5}{\sqrt{x}} \text{ Hz} \quad (9)$$

where x , in centimetres, is the static displacement of a vibration-isolated object (the difference between positions of vibration isolators in the vertical axis before and after the force application).

In most cases the frequency of technological vibration (forced frequency) during operating conditions is very close to the natural frequency of the vehicles and may cause significant resonances. This feature often determines the application of rubber vibration isolators for off-road vibration reduction that are characterized by substantial stiffness and by a high vibration loss factor. Vibration loss factor (η) in rubber vibration isolators may reach values $\eta = 0.2$ to 0.4 providing reasonable attenuation in resonance conditions.

Vibration damping is used to reduce structure-borne noise excited in plane metal shielding elements of a cab (e.g. sheet metal panels). Vibration damping coverings are characterized by high internal friction. The damping covering is usually in 1.5 to 2 time thicker than a treated metal sheet. Sandwich constructions are used in some cases when surface friction between two metal constructions is applied and as a partition between the diesel compartment and a cab in off-road vehicles. An additional effect of noise reduction is obtained due to

the lowering of structure-borne sound and the reduction of resonance effects in metal panels.

CHAPTER 99

AIRCRAFT CABIN NOISE AND VIBRATION PREDICTION AND PASSIVE CONTROL

John F. Wilby
Wilby Associates
Calabasas, California

1 INTRODUCTION

Aircraft cabin noise can be generated by a variety of sound and vibration sources and transmitted into the cabin by airborne and structure-borne paths. The sources may be inside or outside the fuselage and, depending on the type of airplane, can include engines, propellers, turbulent boundary layer, air-conditioning systems, and propulsion system gearboxes. The main airborne noise transmission path is through the sidewall of the cabin and can involve resonant and nonresonant components. Structure-borne paths are usually associated with vibration excitation at different locations on the airframe. Potential sound and vibration sources, and their transmission paths, are described in this chapter, and methods of identifying the contributions from the different sources and paths are discussed. Passive control of cabin noise levels can be achieved by reduction of the source or by attenuation during transmission; various methods for achieving passive noise control are identified. Finally, analytical methods for the modeling of noise transmission into an airplane cabin, including modal methods, statistical energy analysis, and numerical methods, are discussed. Active control of aircraft cabin noise is discussed in Chapter 100.

2 NOISE AND VIBRATION SOURCES

Several sources contribute to cabin interior noise and vibration levels.^{1,2} The sources may be external (engines, propeller, turbulent boundary layer) or internal (air-conditioning system, gearbox, etc.) to the fuselage. Typical exterior noise sources are shown schematically in Fig. 1 for two aircraft configurations. Contributions from propeller and engine noise sources are often determined by near-field characteristics that differ from the far-field characteristics of interest to community noise. A complete description of the exterior fluctuating pressure fields for use in the prediction of interior sound pressure levels involves pressure spectra and cross spectra and the spatial distribution over the excitation surface.

2.1 Boundary Layer Fluctuating Pressures

The turbulent boundary layer pressure field on the exterior of the fuselage is the main source of broadband noise in the cabins of many fixed-wing airplanes.^{1,3,4} The turbulent boundary layer is attached over most of the fuselage, but there may be some regions of separated flow in the neighborhood of protrusions and

around the cockpit. Even for subsonic cruise, there may be some areas of supersonic flow with shock waves, particularly above the cockpit. Interior noise generated by the external turbulent boundary layer is usually important in the mid and upper frequency ranges, as is indicated in Fig. 2, which shows interior sound pressure levels measured in a business jet airplane at three Mach numbers.

Separated flow and shock waves cause sound pressure levels at low frequencies to increase relative to those for attached boundary layers.⁵ Wind tunnel and flight measurements have been used to develop semiempirical representations for attached and separated turbulent boundary layer pressure fields that can be used in noise transmission models.^{1,5,6} Interior noise levels are influenced by aerodynamic coincidence, which occurs when the convection speed in the turbulent boundary layer matches the flexural wave speed in the fuselage panels.²

2.2 Propeller Noise

Propeller noise spectra (see Chapter 90) are dominated by discrete frequency components at the propeller blade passage frequency, f_b , and harmonics thereof.^{7,8} The blade passage frequency is given by $f_b = B\Omega/60$ Hz, where Ω is the rotational speed in revolutions/minute [rpm] of the propeller and B is the number of blades. A typical sound pressure spectrum measured in the untreated cabin of an airplane with two wing-mounted turboprop engines is shown in Fig. 3. The broadband noise inside many propeller-driven airplanes is dominated by the turbulent boundary layer rather than the propeller, particularly at higher flight speeds.⁷

Propeller location is a significant factor in determining propeller noise levels in the cabin because of strong directivity characteristics. Airplanes with a single tractor propeller mounted in the nose of the airplane usually have relatively low levels of propeller noise in the cabin, whereas multiengine airplanes with engines mounted on the wing have high cabin sound pressure levels in the vicinity of the plane of rotation of the propeller. Pusher propellers that are mounted aft of the cabin operate in a disturbed flow field and propeller noise radiates forward, impinging on the airplane fuselage.

In the neighborhood of the plane of rotation of the propeller, where the distance between the fuselage and the propeller tip is small relative to the acoustic wavelength, the fuselage is in the acoustic near

Figure 1 Sources and transmission paths of aircraft interior noise. (Reprinted with permission from SAE Paper 820961 © 1982 SAE International.)

Figure 2 Sound pressure levels in business jet airplane at different flight Mach numbers. (Reprinted with permission from SAE Paper 820961 © 1982 SAE International.)

Figure 3 Narrow-band interior noise spectrum for propeller-driven airplane with untreated cabin. (Reprinted with permission from SAE Paper 850876 © 1985 SAE International.)

field or aerodynamic potential field of the propeller, with the source moving with the propeller blade.^{5,9} Elsewhere, the fuselage is in the acoustic far field. Beats will occur in multiengine airplanes if propellers are not synchronized. Also, pressure cancellation and augmentation due to phase differences between propellers can result in rapid spatial variations in interior sound pressure level.

2.3 Jet Noise

Airborne transmission of jet noise is associated mainly with aircraft with wing-mounted engines. It affects cabin regions aft of the engine exhaust and is generally limited to low frequencies.³ Jet noise levels (see Chapter 89) are determined by the relative velocity between the exhaust and the surrounding air and decrease as the airplane accelerates during takeoff and climb. Jet noise spectra are broadband and peak at different frequencies for different locations in the near field.⁵ The spectra can be normalized in terms of a nondimensional frequency using jet nozzle diameter, D , and jet velocity, U_j , as the normalizing parameters, and the pressure cross spectrum can be represented by a simple formulation for use in analytical models.⁵

2.4 Engine Fan Noise

Fan noise from a turbofan engine can be transmitted into the fuselage interior, particularly at locations forward of the engine inlet, but the contribution to cabin sound pressure levels is significant only at low flight speeds such as takeoff and initial climb.^{3,10} Fan noise is associated with the blade passage frequency of the fan and with multiple pure tones (or buzz-saw)

created by shock waves generated in the supersonic flow region of the fan blades. The fundamental frequency of multiple pure tones is $f_{mpt} = \Omega/60$ Hz, but the fundamental and lower order harmonics are below the inlet duct cutoff frequency and do not radiate from the inlet.

2.5 Engine Vibration

Out-of-balance forces from reciprocating and jet engines excite the mounting structure with resultant sound radiation into the fuselage interior. This is especially true when jet engines are mounted on the rear of the fuselage, as they are closely coupled to the fuselage structure¹¹ but may also be true in the case of wing-mounted engines even though the mounting structure is more massive.² Turbofan out-of-balance forces are usually dominated by the fundamental component that occurs at the rotational frequency of the fan, compressor, or turbine. Figure 4 shows a narrow-band sound pressure spectrum measured in the cabin of a business jet airplane with two turbofan engines mounted on the rear of the fuselage.

Discrete frequency components are observed at the rotational frequencies of the fan, f_b , low-pressure turbine, f_l , and high-pressure turbine, f_h , plus harmonics of the fan and low-pressure turbine. The sound pressure levels are sensitive to small changes in engine balance and the airplane structure, with the result that they vary markedly from airplane to airplane and are difficult to predict. Vibration-induced noise from reciprocating engines can occur in general aviation airplanes at the same discrete frequencies as the propeller blade passage frequency and its harmonics.^{12,13}

Figure 4 Narrow-band interior noise spectrum for business jet airplane. (Reprinted with permission from SAE Paper 820961 © 1982 SAE International.)

2.6 Reciprocating Engine Noise

The exhaust outlets of reciprocating engines on small general aviation aircraft can be close to the airplane cabin. The fundamental frequency for a single cylinder is $f_c = \Omega/120$ Hz, and the fundamental frequency for the total exhaust is $f_e = N_c \Omega/60$ Hz, where N_c is the number of cylinders. The magnitude of the noise level depends on the design of the exhaust system and the effectiveness of any muffler.

2.7 Wake-Structure Interaction

Interaction between a propeller wake and the wing or horizontal stabilizer structure downstream of the propeller can cause vibration that is transmitted to the airplane cabin and radiated as sound.^{1,2} The components of wake-induced noise will be at the same frequencies as the components of propeller noise.

2.8 Helicopter Rotors and Gears

Helicopter main and tail rotors (see Chapter 91) contribute to helicopter interior noise levels.¹⁴ Since discrete frequency noise from rotors is radiated mainly in directions close to the plane of rotation, the tail rotor may make a greater contribution to cabin noise levels than does the main rotor. Several factors determine the relative magnitudes of main and tail rotor noise in the cabin, including the distance of tips of main and tail rotors from the cabin, the directivity of rotor noise fields, and attenuation characteristics of the cabin sidewall.

The gearbox of a helicopter is a major source of cabin noise.^{1,14} It is usually mounted close to the cabin, with strong airborne and structure-borne transmission paths into the cabin. Gear noise (see Chapters 69 and 88) occurs at the teeth-meshing frequencies and harmonics thereof.

2.9 Internal Noise Sources

Noise sources inside an aircraft include air-conditioning systems, hydraulic systems, pressure relief valves, vents and drains, and electrical and mechanical equipment. Noise sources in an air-conditioning system include the air cycle machine, fans, valves and orifices in the ducts, separated flow in duct bends, and high-velocity flow through air grilles.¹⁵ Noise sources in a hydraulic system include pumps and valves.

3 TRANSMISSION PATHS

Transmission paths from source to cabin interior can be classified as either airborne or structure borne (Fig. 1). A flow diagram can be constructed to show the different paths.¹

3.1 Airborne Paths

Airborne noise is associated with noise transmission from an acoustic or aerodynamic pressure field through a structure into the cabin. The transmitting structure could be the fuselage sidewall, when the noise source is external to the fuselage, the floor of the cabin when the noise source is in an underfloor compartment, or the cabin wall of a helicopter when the noise source is

inside the fuselage shell but outside the cabin. Critical airborne noise transmission paths occur where the noise control treatments are compromised.¹⁶

Airborne noise transmission can have two components—resonant and nonresonant transmission. Nonresonant transmission is the mass-law transmission that is familiar in architectural acoustics and can be important for an acoustic source. Resonant transmission is the dominant airborne transmission path associated with turbulent boundary layer excitation and with acoustic excitation at frequencies above coincidence. Acoustic coincidence occurs when the speed of sound in air equals the flexural wave speed in the structure.

Fuselage structures respond differently to turbulent boundary layer excitation and acoustic excitation.^{1,2,4,17} Acoustic excitation is highly correlated over large distances and can excite large regions of the structure including frames and stringers.¹⁷ In contrast, turbulent boundary layer excitation is uncorrelated over large distances, particularly in the circumferential direction, and fuselage response shows little correlation between adjacent panels.¹⁷ Similarly, noise transmission characteristics are different for the two types of excitation.

3.2 Structure-Borne Paths

Structure-borne noise is associated with vibrational energy that is transmitted through the structure from external sources and then radiated into the cabin as sound. Sources that generate structure-borne noise include out-of-balance forces in the engine,^{2,11,12} propeller wake interacting with the wing or tail surfaces, air cycle machines¹⁵ or hydraulic pumps beneath the cabin floor, and gearboxes mounted outside the cabin of a helicopter.¹⁴ The spectrum in Fig. 3 contains a structure-borne component, at a frequency of 669 Hz, associated with engine turbine out-of-balance forces. This component was transmitted through the engine mounts and wing structure to the fuselage. In the case of mechanical excitation, the vibration power transmitted from the source to the aircraft structure is a function of the point impedances of the source and structure at the excitation location, as well as the magnitude of the excitation force.¹

3.3 Cabin Cavity

Although not often considered as part of the airborne or structure-borne transmission paths, the acoustical characteristics of the cabin cavity do play a role. Analytically, acoustical modes of a cabin are important in the prediction of cabin noise levels. However, there are few reports in the literature regarding actual measurements of the acoustical characteristics of a furnished aircraft cabin. Occasionally, evidence of standing waves has been found, but those events were typically associated with unfurnished or partly furnished cabins.^{1,7} For example, it was speculated that acoustic resonances influenced the poor repeatability of cabin noise levels in an unfurnished propeller-driven general aviation airplane, where the noise spectrum was dominated by discrete frequency components.⁷

Sound absorption provided by cabin furnishings is sufficient, in most cases, to damp out acoustic resonances. Analysis has indicated that a sound absorption coefficient greater than 0.2 is sufficient to suppress acoustic modes in a cabin.¹

4 SOURCE/PATH IDENTIFICATION

Identification of noise sources or transmission paths can be performed by experiment, analysis, or a combination of both.¹⁸ It is often found that no single approach is adequate—a combination of a number of methods may be necessary.

4.1 Source Identification

Frequency Identification When sources have well-defined frequency components that are distinct from those of other sources, components in the narrow-band spectra (see Chapter 46) of cabin noise can be used as source identifiers. Such is the case for propeller noise and noise due to engine out-of-balance forces (Figs. 3 and 4). However, spectral analysis cannot distinguish between contributions from different sources operating at precisely the same frequency.

Correlation The separation of jet noise and turbulent boundary layer contributions to the fluctuating pressures measured on the exterior of an airplane is difficult because both contributions are broadband. However, the two contributions to the exterior pressure field can be separated by the use of cross-spectrum or correlation techniques.¹⁰ Correlation techniques cannot be used with sinusoidal signals because the signals are always fully coherent. However, partial coherence techniques have been successful when there are two discrete frequency sources with very close, but not identical, frequencies.¹⁹

Source Modification Source modification involves changing the operating conditions of one or more noise sources and measuring the resulting changes in cabin sound pressure levels.^{1,20} However, it should be recognized that changes to the operating condition might change the contributions from other sources. For example, propellers of a twin-engine airplane can be operated at slightly different rotational speeds. The advantage of the method is that the contributions from the two propellers can be identified without a significant change in air speed.⁷ The disadvantage is that the method eliminates destructive or constructive interference between sound pressures from the two sources that might occur in normal operation. Alternatively, engine power can be varied and the aircraft allowed to climb or descend through specified values of altitude and speed to determine engine noise contributions.²⁰

Source Elimination The effect of eliminating a noise source is similar to that of source modification, and the advantages and disadvantages are also similar. For example, all engines can be set to flight idle and the airplane placed in a shallow dive to measure turbulent boundary layer noise.^{8,12,20} The disadvantages of this

method are that the airflow over the airplane may change, and cruise flight speed will not be maintained. In a second example, internal equipment, such as the environmental control system, can be turned off and cabin noise levels measured.²⁰

4.2 Path Identification

Path identification is critical to the optimum implementation of noise control measures. However, direct measurement of structure-borne noise is difficult because it requires, in part, measurement of power flow in flexural, longitudinal, and torsional waves. Consequently, other approaches have been used. Path identification methods are often experimental in nature, but the supplemental use of analytical methods can be useful.¹

Source Simulation Ground tests can be performed using sound (loudspeaker) or vibration (shaker) sources or an actual propeller to simulate the in-flight source.^{1,21} The sound source can be placed in an enclosure so that the area of exposure on the fuselage can be limited to a window or other small region of interest.¹ Alternatively, an array of loudspeakers with phase control can be used.²² Shakers can be placed at engine mounts or other locations.

Acoustical Enclosure An enclosure can be used in the cabin to limit the area of sound radiation and investigate noise transmission paths. The enclosure should be constructed to minimize sound transmission through the walls and to prevent reverberant buildup inside.

Path Interruption The path interruption method usually requires tests on a stationary airplane on the

ground or in the laboratory.^{1,13} The assumption is made that the results obtained from the ground tests are still valid in flight. For a propeller-driven airplane with a single engine, the engine can be mounted on supports and operated when it is connected and disconnected to the fuselage.¹³ In the case of propeller wake interaction with the airplane wing, the wing can be detached from the fuselage structure or enclosed in a sleeve that isolates the wing structure from the fluctuating pressures in the propeller wake.¹

Path Modification Changes in a transmission path may alter the transmitted noise sufficiently to infer the importance of that path. The method assumes that airborne and structure-borne noise components are statistically independent, which may not be true when discrete frequency components are involved. A common technique in path modification is the use of heavy mass-loaded vinyl sheets to cover cabin surfaces of interest.^{1,20} It is possible that sound pressure levels might increase at some frequencies because of a decrease in sound absorption in the cabin or blockage of a transmission path to the exterior.

For structure-borne noise transmission from an engine, the standard isolation mounts for the engine can be replaced with solid metal blocks and the tests repeated.¹² Figure 5 shows the results from a test on a single-engine, propeller-driven airplane.¹² Sound pressure levels were measured in the airplane cabin and vibration levels were measured on the airplane structure near to the engine mounts. When the engine isolation mounts were replaced with hard mounts, the structure-borne vibration increased by up to 25 dB, but the cabin sound pressures increased by a maximum of only 7 dB. The results imply that the

Figure 5 Change in cabin sound pressure level and structural vibration level when engine isolation mounts are replaced with solid metal blocks on a single-engine propeller-driven airplane.¹²

cabin sound pressure levels are controlled by structure-borne vibration transmission only in the frequency range below about 400 Hz.

Transfer Function Methods The transfer function method is applied in three steps.¹ First, the transfer function between the source of interest and cabin noise levels is obtained. Second, the source level under flight conditions is measured. Third, the product of transfer function and flight source level is calculated to obtain an estimate of interior noise level in flight due to that source. The first step is usually performed in a nonoperational environment when no other sources are present. The accuracy of the third step depends on the validity of the assumption that the imposition of flight loads does not change the transfer function.

In the case of structure-borne engine noise, a transfer function relating structural acceleration at the engine mount to cabin interior sound pressure levels is measured during ground tests.¹² That transfer function is then applied to in-flight measurements of vibration to estimate the contribution to cabin sound pressure levels. The transfer function method can also be used to estimate the cabin noise components associated with wing vibration induced by propeller wake impingement. Shakers are used to induce vibration into the wing structure while sound pressure levels are measured in the cabin. Then, wing vibration is measured in flight. If measurement of the transfer function is not feasible, it may be possible to use the principle of reciprocity, which can be applied to acoustical or mechanical sources.¹

Intensity Sound intensity methods (see Chapter 45) can be used to determine the relative importance of noise transmission paths.^{1,18,20} The surfaces of interest in the cabin (sidewall, floor, ceiling, windows, etc.) are divided into small areas. The intensity probe is then traversed over each subarea to determine the sound power transmitted through that subarea.

Acoustical Holography Near-field acoustical holography (see Chapter 50), in conjunction with boundary element methods, can be used to investigate fuselage vibration and interior sound fields.¹ The method has been applied, for example, in a turboprop airplane to the blade passage frequency and its first two harmonics.²³

5 PASSIVE NOISE CONTROL

A successful passive noise control program often has to address several noise sources and transmission paths. A balanced noise control treatment would consider all combinations of sources and paths such that all contribute approximately equally. Reducing the noise from one source to a level well below the contributions for the other sources would not be cost or weight effective. A successful noise reduction program often requires a combination of test and analysis.¹⁸

5.1 Reduction at Source

Reduction of Propeller Near-Field Noise Levels

Cabin noise levels can be reduced by increasing the

clearance between the propeller tip and the fuselage and decreasing the propeller tip Mach number.²⁴ This could require an increase in the number of propeller blades or relocation of the engines further outboard. Direction of rotation may be a factor in determining interior sound pressure levels; a solution would require that propellers on opposite sides of the fuselage rotate in opposite directions.²⁴

Engine Balancing The out-of-balance forces imposed by turbofan engines can be reduced by improving the balancing of the rotors, particularly the fan as it is the most massive of the rotors.²⁵

5.2 Reduction in Transmission

The most effective way to reduce noise transmission is to modify the transmission path as close as possible to the source, for example, at the mounts of an engine or air cycle machine. In principle, this is true for both airborne and structure-borne transmission, but it is more difficult to achieve in the airborne case because the noise sources are usually distributed over a large surface area, whereas sources of structure-borne noise tend to be local and well defined.

Sidewall Cabin sidewalls are generally constructed from multiple layers of porous material. A simple sidewall is depicted in Fig. 6 where porous material is placed between the fuselage frames and over the frames.^{1,16} The porous material typically consists of glass fiber blankets with a density of about 7 kg/m³. This is a compromise between weight and

Figure 6 Cross section through typical cabin sidewall treatment. (Reprinted with permission from SAE Paper 820961 © 1982 SAE International.)

transmission loss. Heavier blankets could be used if additional transmission loss is required. The blankets are contained in impervious bags to prevent moisture retention. A sheet of heavy, limp material can be placed between layers of the porous material to increase sound transmission loss. A trim panel is attached to the frames to cover the porous material. The attachment should be by means of vibration isolation mounts, to prevent structure-borne paths that would short out the acoustical insulation.¹⁶ Sound transmission through a cabin window can be reduced by increasing the thickness of the window pane.¹⁸

Sound Absorption Sound absorption is provided in the cabin by the carpet and seats. Additional sound absorption may be obtained by treatment of the ceiling and bottom of the stowage bins. Sound absorption material is often required in the neighborhood of entry doors and in galleys.¹⁶

Damping Material Damping material (see also Chapter 60), often in the form of constrained layer damping tape with a viscoelastic adhesive and an aluminum foil backing layer, has been used to reduce airplane interior noise.^{16,26} Usually, damping material is applied to fuselage skin panels where it is effective mainly at frequencies above the panel fundamental frequency, but the effectiveness might be extended to lower frequencies by application of damping material to frames and stringers.^{27,28} Damping material can also be applied to trim and floor panels.^{20,29}

Optimized damping tape treatments cover about 80% of the panel area.^{26,29} However, the effectiveness can be increased by the use of a spacer between the structure and the viscoelastic layer, and the area covered can be reduced.¹⁸ Damping materials should

be selected for the operating temperatures of the structure being treated.

Figure 7 shows the reduction in cabin noise obtained by the use of damping tape on an airplane pressurized fuselage excited by a turbulent boundary layer.²⁶ In this case, all cabin furnishings, including sidewall insulation, had been removed. The damping tape was applied to about 80% of the panel area. In addition to the increased damping, the tape also increased the mass of the fuselage panels by about 10%. Significant noise reductions occur only in the frequency range of 1000 to 4000 Hz, which is the frequency range of the lower order modes of the individual panels of the pressurized fuselage and the frequency range in which there is good coupling between the excitation and the structure (known as aerodynamic coincidence).

Isolated Shell A self-supporting isolated interior shell can be constructed to reduce structure-borne noise transmission.^{25,30} The interior shell is mounted on vibration isolators placed on the floor, or on frames near to the floor, where the vibration levels are low. The number of attachment points should be kept to a minimum and the isolators designed for maximum effectiveness.

Dynamic Absorbers and Tuned Dampers These resonant devices (see Chapter 61) can be used to reduce interior noise levels of aircraft where the excitation is discrete frequency.² Dynamic absorbers are effective only in a narrow frequency band and are used mainly in cases where the propeller or engine rotational speed is essentially constant over much of the flight regime. A tuned damper can have a greater effective bandwidth, but at the expense of less attenuation.³¹ When more than one frequency is to be attenuated, sufficient damping

Figure 7 Effect of damping tape on sound pressure level in an unfurnished pressurized fuselage exposed to turbulent boundary layer excitation.²⁶

has to be introduced to broaden the attenuation peak, or different absorbers have to be designed for each frequency of interest. Dynamic absorbers or tuned dampers have been installed at the attachment location of rear-mounted turbofan engines,¹¹ on fuselage frames to reduce the propeller noise transmission,^{31–33} or on trim panels in the cabin.^{32,33}

Engine Mounts Passive engine mounts are usually proprietary designs of viscoelastic material or metal, and represent a compromise between static and dynamic stiffness. The static stiffness has to be sufficient to withstand the static loads imposed by engine weight and thrust without shorting out, while the dynamic stiffness has to be low enough that the vibration is not transmitted into the fuselage structure (see Chapter 59). The effectiveness of the mounts can be increased by increasing the input impedance of the airplane structure.

Propeller Synchronphasing Adjustment of relative phase angles among the propellers, often referred to as “synchronphasing,” can reduce cabin sound pressure levels.^{1,24,32} The potential for noise reduction appears to be greater for four-engine aircraft than for two-engine aircraft because there are more possibilities for cancellation.

Mufflers and Suppressors Noise transmission can be attenuated by the use of mufflers (see also Chapter 85) in reciprocating engine exhausts, air cycle machine ducts, and drain and vent systems. Pulsation dampers or surge suppressors can be installed to attenuate hydraulic pump noise. Sound-attenuating material can be placed in the return air grilles of the environmental control system.²⁰

Acoustic Leaks It is critical that all acoustic leaks be identified and eliminated because leaks severely degrade the performance of noise control treatments.

6 ANALYTICAL METHODS

Several different approaches can be applied to the analytical modeling of airborne and structure-borne noise transmission into airplanes. The choice of a particular method is often determined by the frequency range of interest because it determines, to some extent, the computational requirements and the validity of the assumptions in the model. The main methods used are closed-form modal approaches, power balance methods, statistical energy analysis, and numerical methods.

6.1 Modal Methods

The modal approach is based on modal representations of the fuselage structure and interior cavity.³⁴ The approach can be combined with the power balance method³⁵ or the traveling-wave approach.³⁶ At high frequencies, the power balance approach merges into statistical energy analysis. The fuselage structure can be modeled as a simple cylinder or as a cylinder with an integral floor.³⁷ At low frequencies, stiffeners can be represented as discrete elements or “smeared” over the fuselage panels to give effective orthotropic panels. At high frequencies, the influence of the stiffeners

can be neglected and the structure divided into a number of substructures. The cabin volume can be modeled as a closed-form modal representation, or finite difference numerical methods can be used.^{37,38} Sound transmission through the cabin sidewall can be modeled separately using the transfer impedance method of architectural acoustics or as an integral part of the sound transmission model.³⁷

6.2 Statistical Energy Analysis

Statistical energy analysis (SEA) methods (see Chapter 17) can be used when there is a sufficient number of modes (say three or more) in any given frequency band of interest, usually a one-third octave band.^{1,5} SEA has been applied to the transmission of jet noise, turbulent boundary layer noise, engine vibration, and propeller noise into an airplane fuselage, with the understanding that there will be an increased variance in the results at low frequencies where there are few modes. In order to mitigate the scarcity of modes, the size of the subsystems in an SEA model should not be too small.^{16,39,40}

Statistical energy analysis assumes resonant response of a structure or cavity. This is adequate for aerodynamic excitation such as a turbulent boundary layer, but in the case of acoustic excitation, the nonresonant or mass-law path has to be included.¹ In the case of aircraft with long cabins, the cabin can be divided into several sections, using physical bulkheads where possible.^{16,39}

6.3 Numerical Methods

Numerical methods (see Chapter 7) generally involve finite element methods (FEM) and boundary element methods (BEM). Most applications to aircraft cabin noise involve FEM-FEM coupled analyses where finite element methods are used to model both the aircraft structure (including the multilayer sidewall) and the cabin cavity. However, boundary elements can be used to model the acoustic radiation into the cabin in FEM-BEM analyses.⁴¹ Numerical methods are usually restricted to low frequencies so that the model does not become excessively large or require too much detail. Consequently, the methods are used mainly to analyze airborne and structure-borne transmission of propeller noise and engine vibration.

It is possible to model the entire cabin of a small aircraft, but models for larger aircraft are usually restricted to a section of the cabin.^{9,21,40} Reductions in model size can be achieved using symmetry of the fuselage to model only one half. In that case, the computations are performed first for symmetrical modes and then repeated for antisymmetrical modes. The model should include some representation of structures adjacent to the cabin.⁴⁰

CHAPTER 100

AIRCRAFT CABIN NOISE AND VIBRATION PREDICTION AND ACTIVE CONTROL

Sven Johansson, Lars Håkansson, and Ingvar Claesson

Department of Signal Processing
Blekinge Institute of Technology
Ronneby, Sweden

1 INTRODUCTION

Low interior noise is important to passenger and crew comfort in aircraft. High noise levels are disturbing, tiring, and reduce the ability to converse with passengers in adjacent seats. The noise levels should not be intrusive and should not have discernible discrete tones, beats, or pulsations. The cabin noise is mainly created by the aircraft's propulsion system and turbulent boundary layer pressure fluctuations, which excite the fuselage and produce fuselage vibrations, resulting in the creation of the cabin sound field. The degree to which noise may be reduced in an aircraft at low frequency is determined primarily by the stiffness and weight of the structure of the fuselage. A general problem is that the noise transmission loss of the fuselage structure is rather small in the low-frequency range. One method of reducing cabin noise in this frequency range is to adopt active control techniques. These techniques are based on introducing secondary sources for controlling the interior cabin sound field or the structural fuselage vibrations. The latter technique reduces the sound radiation into the cabin. The active control systems for reducing tonal cabin noise are generally based on either active noise control or active structural acoustic control. One may attenuate broadband cabin noise with the aid of active headsets or silent seats.

2 CABIN NOISE AND VIBRATION SOURCES

Both internal and external sources cause noise and vibration in an aircraft.^{1–5} One internal noise source is the air-conditioning system; the most predominant sources, however, are external. There are several external sources of noise and vibration in an aircraft: engines, propellers, jet engine fans, the boundary layer, and the like. Each source has its own characteristics and transmission paths into the cabin, for example, airborne paths and/or the structure-borne paths.^{1–3} Figure 1 illustrates the sources of noise and vibration in an aircraft and their transmission paths into the cabin.

The main source of cabin noise in turboprop aircraft is the airborne noise produced by the propellers.^{1,2} The propeller blades pass the fuselage, thereby producing periodic pressure fluctuations on the external of the fuselage; this in turn causes vibrations in the internal cabin walls and an excitation of the interior cabin sound field. The structural vibration modes coupled to the interior acoustic modes result in a transfer of energy from the fuselage outside into the cabin.^{6,7} Cabin

Figure 1 Sources of noise and vibration in an aircraft and their transmission paths.³

noise in turboprop aircraft usually takes the form of tonal noise related to the fundamental blade passage frequency (BPF). The dominant frequency components are generally in the frequency range of 60 to 400 Hz; the blade passage frequency and two or three of its harmonics predominate.^{1,2} Figure 2 shows a typical spectrum of the cabin noise level in a turboprop aircraft during cruise flight. Generally, aircraft are equipped with a synchronization unit to synchronize the rotational speed of the propellers. Any difference in the rotational speed leads to unpleasant acoustical beating.¹

For high wings and tail aircraft designs with small propeller tip clearance, the transmission paths of the propeller noise are dominated by the airborne path between the propeller and the fuselage.^{3,8} For aircraft with low wings and tail, the turbulent airstream behind the propeller is also a significant excitation factor. The airstream excites the wing and tail structure, causing complex transmission paths of propeller-induced noise into the cabin. In jet aircraft, airborne transmission of noise is generally associated with aircraft with wing-mounted engines; in this type of aircraft, the broadband jet noise affects cabin regions aft of the engine exhaust, particularly when the engines are mounted close to the fuselage.^{2,5}

Imbalances in rotating parts of an aircraft propulsion system excite vibration of the fuselage via the

Figure 2 Sound pressure level spectrum for typical cabin noise in a turboprop aircraft.

engine-supporting structure, and the fuselage structural vibration radiates noise into the cabin; such noise is called *structure-borne noise*.^{1,2} In the case of turboprop propulsion systems, the gearbox normally excites the structure and produces gear whine at frequencies on the order of hundreds of hertz,¹ and propeller imbalance produces vibrations from 15 to 20 Hz.¹ In jet aircraft with tail-mounted engines, the principal structure-borne noise excitation source is the two spools of each jet engine; these normally run between 100 and 500 Hz.^{1,2,5}

Boundary layer noise, or wind noise, is audible in all aircraft.^{1,2,5} During flight, the interaction between the surrounding air and fuselage wall induces turbulence pressure fluctuations that act on the external fuselage along the length of the aircraft; this in turn radiates noise into the cabin. Particularly high levels of boundary layer noise are created at any point on the outer fuselage where the shape of the skin changes abruptly, for example, antenna fairings. Boundary layer noise is highly dependent upon the flight speed and is of a random broadband nature, the majority of its energy being above approximately 400 Hz.^{1,2} With decreasing levels of propulsion-induced cabin noise, the boundary layer noise becomes increasingly apparent.²

3 ACTIVE CONTROL OF NOISE

3.1 Noise Control Introduction

Cabin noise in aircraft is often difficult to attenuate adequately by means of passive noise control approaches due to weight restrictions.^{1,3,4} A common passive method is to increase the dynamic stiffness of the fuselage by using passive-tuned vibration dampers.^{1,7–9} This method is based on the principle

that passive-tuned dampers attached to the fuselage structure absorb vibration energy at the resonance frequency, thereby reducing noise transmission into the cabin.^{4,8} The dampers are tuned to reduce vibrations at a specific frequency, for example, the BPF for cruise flight, and are unable to track frequency variations. Generally, the first few harmonics of the BPF may be significant, and to reduce several harmonics a large number of dampers tuned for different frequencies must be used; this adds significantly to the weight of the aircraft.⁴ Furthermore, the engines may be run at different speeds in different parts of the flight cycle. In contrast to the passive dampers, the active control system is usually synchronized with the engines and is able to track variations in noise; attenuation is maintained throughout the flight cycle, including cruise, climb, and descent.^{4,8} If the controller is synchronized with both engines, the acoustical beating that appears as the engines become unsynchronized is also controlled. Even with many secondary sources, the active control system adds less weight to the aircraft than does a normal set of passive-tuned dampers.⁸

3.2 Active Control

The basic principle of active control is to introduce secondary sources for controlling either the sound field or the structure radiating the noise.^{6,7,10,11} If a few, well-defined transmission paths of noise into the cabin are established, it is possible to act directly on the transmission paths to reduce noise transmission.^{5,6,8,12–15} On the other hand, if the transmission paths are complex or unknown, the noise is controlled after its transmission into the cabin by using loudspeakers mounted in the trim.^{4,8,10,12–15} Strategically located

error sensors are used to allow continuous adaptation of the control system driving the control sources.^{10,16} The error sensors are usually composed of microphones mounted in the trim that observe the cabin sound field. The objective of the active control system is to minimize the sound pressure in the error microphones.^{10,16} One commonly used objective is to minimize the squared sound pressures measured in the error microphones. Figure 3a shows an illustration of an active noise control system synchronized with both engines. In situations where the aim is to reduce the sound radiation from the fuselage, the loudspeakers are replaced with structural actuators controlling the fuselage vibrations^{6,8,14}; see Fig 3b.

The sound field in the cabin, or in an enclosure, can be viewed as the superposition of the acoustic modes.^{6,7,10} Each mode is related to a resonance frequency of the enclosure, and the mode shape describes the spatial pattern of pressure, maximum and minimum, that is, antinodes and nodes. Active control of the disturbing acoustic modes is achieved by introducing loudspeakers. The purpose of the loudspeakers is to produce independent modal responses that are of equal amplitude and opposite phase to each of the corresponding uncontrolled disturbing acoustic modes.¹⁰ Normally, at low frequencies a few modes dominate the sound field; these modes are usually well separated. Controlling noise fields characterized by separate modes results in large volumes of noise attenuation, so-called global control. The objective with global control of enclosed sound fields is to reduce the total acoustical potential energy in the enclosure.¹⁰ In fact, it turns out that such a strategy has the effect of leveling out the

spatial variation of the pressure level in the enclosure since dominant acoustic modes are suppressed.

At higher frequencies, the distance in frequency between two adjacent modes becomes smaller and smaller and many modes contribute to the sound field.¹⁰ The modal density increases and the individual modes will be indistinguishable. As the frequency increases, the sound field is changed from modal type to be considered diffuse with high modal overlap.¹⁰ Since the modal density and modal overlap are high, global control is not possible at these frequencies; however, local active noise control is possible under such circumstances.¹⁰ Global reduction is possible only if the secondary source is placed very close to the primary noise source.¹⁰ This is not possible in the aircraft applications. Local control is based on the strategy to achieve local areas of reduced noise, for example, a localized zone of “quiet” around the head of a seated passenger. The zones with reduced noise will be found close to the control microphones, and the size of the quiet zones are highly dependent on the frequency: The size of the zone decreases with increasing frequency.¹⁰ Accordingly, local control requires that the control microphones be located in the vicinity of the passengers’ head positions, for example, on the headrests instead of the trim. The local control of sound fields is used in the silent seat application where each seat is equipped with individual loudspeakers and microphones in the headrest.^{10,12}

Structural actuators may also be applied as secondary sources in active control of acoustical noise in aircraft.^{6,8} This method is used when there are some dominant noise transmission paths into the cabin.

Figure 3 Active control of aircraft interior noise: (a) active noise control system in a turboprop aircraft, and (b) active structural/acoustical control in a jet aircraft.

The structural aircraft fuselage vibrations produced by the propulsion system and pressure fluctuations from the propellers acting on the external fuselage generally excite the interior cabin sound field. The purpose of applying structural actuators is to apply control forces to the fuselage, thereby controlling the structural modes of the fuselage associated with significant sound radiation into the cabin.¹⁰

The structural actuators are located in the dominant noise transmission paths to reduce the sound transmission through the structure.^{5,8,10} The disadvantage of this approach is that any noise reaching the cabin via other transmission paths cannot be controlled. Such noise is controlled inside the cabin. The active structural/acoustical controlled approach reduces the dominant acoustically coupled structural modes, which normally results in global noise attenuation.⁶ A comparison between the active noise control approach and the active structural/acoustical control approach usually shows that fewer secondary structural actuators than loudspeakers are used for a global control of the interior cabin sound field.^{6,12}

The error sensors are again microphones to adapt the control system. Thus, where the aim is to reduce the sound pressure level, it is recommended to use error microphones, which observe the interior sound field, rather than error accelerometer sensors, which observe structural fuselage vibrations.⁶ The minimization of vibrations at selected points, that is, the accelerometer positions, does not necessarily guarantee the reduction of sound radiated into the cabin. In fact, minimizing local vibrations often leads to an increased sound pressure level.⁶ One disadvantage of the active structural/acoustical control approach is that even though the noise level is reduced, the structural vibrations can sometimes increase.⁶

The active control of acoustic and structural modes may influence nondisturbing modes.^{6,10} Modal density increases with increasing frequency, and a higher modal overlap is obtained. As a consequence, the influence of control source excitation of nondisturbing modes also increases. This control spillover reduces the effect of the active control system.^{6,10} The modal overlap^{6,10} for acoustic modes increases rapidly with frequency and is roughly proportional to f^3 , while the modal overlap for the flexural structural modes demonstrates a less pronounced increase with frequency, approximately proportional to f . Structural control enables global control of the sound field at higher frequencies than may be achieved with control of the acoustic modes.^{6,10} High modal overlap and control of the acoustic modes result in local control around the error microphones.¹⁰

3.3 Active Control Strategies

The active control strategy used to attenuate cabin noise in aircraft depends primarily on the type of propulsion system, transmission paths, aircraft design, and noise characteristics. In commercial aircraft, one of two different kinds of large-scale (multichannel) active control strategies is normally used today to control tonal cabin noise. Both strategies are of adaptive

feedforward type and use error microphones to observe the controlled sound field. The ANC (active noise control) system uses loudspeakers as secondary sources while the ATVA (active tuned vibration absorber) system uses inertial mass actuators as structural secondary sources.^{4,5,8,14,15} The principle of ATVA is similar to that of the ASAC (active structural/acoustical control) approach described in the relevant literature.⁶ In recent years, active headsets have been introduced in the first- and business-class cabins of wide-bodied jets.¹² The headsets are directed toward the control of broadband noise found on wide-bodied jet aircraft. These headsets are based on feedback control and normally rely on analog control.^{7,10,17}

Global Control Approaches ANC has proved effective and will continue to be the favored option on turboprop aircraft with complicated and/or multiple noise transmission paths into the cabin. Examples of such aircraft are the Saab 340 and Saab 2000.⁴ The Saab 340 was the first commercially available aircraft in the world in which ANC was used; the first aircraft was delivered in the spring of 1994. The first Saab 2000 was delivered later the same year.¹⁸

A low wing and, in particular, low tail (directly acted on by the propeller backwash) combined with a low tip clearance result in a variety of noise paths; methods that act directly on these paths are thus both problematic and expensive.^{4,8} On the other hand, ATVA is used commercially on both turboprop and jet aircraft. The ATVA approach is used on the turboprop aircraft in the Bombardier Q series Dash-8.^{8,14} These aircraft have high wings and tail and a small propeller tip clearance. Here, the predominant transmission path consists of the direct action of the propeller wash on the fuselage in and around the plane of the propellers. The ATVA approach has also been successfully applied to jet aircraft. In jet aircraft, out-of-balance forces from the engine shafts excite the fuselage via the engine mounts and pylons (the predominant transmission paths) thereby causing vibration-induced noise within the aircraft cabin.^{5,12-15} The active control performance for different control strategies are presented in Table 1.

Local Control Approaches In recent years, active headsets—normally integrated into the passenger entertainment system—have been introduced into the first- and business-class cabins of wide-bodied jets.¹² Also, quiet seats creating a localized zone of noise attenuation around the passenger head by using active digital feedback control have been developed for wide-bodied jet aircraft.^{12,14} Both active headsets and quiet seats alleviate the problem of broadband noise on wide-bodied jet aircraft, a noise that is less dominated by the tones found in turboprops and jet aircraft with tail-mounted engines.

3.4 Multichannel Adaptive Feedforward Control

To obtain a significant global noise reduction in a large cavity such as that found in aircraft cabins, a large

number of control sources and error sensors are generally needed.¹⁰ For a twin-engined aircraft, the control system and the algorithm must also be able to handle two synchronization signals, one from each engine, to control individually the noise from the two sources.^{8,10} The reference signals to the feedforward controller, which are generated from the synchronization signals, contain the same frequencies as the noise components to be suppressed, for example, the BPF and its harmonics. With reference signals generated in this manner the control becomes selective.^{7,11,16} It is possible to determine which of the harmonics are to be controlled and which are not.

The control algorithm is the part of the total control system that takes up the major part of the processor capacity; it is thus extremely important to use an algorithm with low computational complexity. The capacity of an adaptive control system to handle tonal components that are close in frequency is dependent on the structure of the controller, that is, how the multiple frequencies are processed.¹¹ The controllers are generally based on either a single-filter structure or a parallel-filter structure using several filters.¹¹ The single-filter structure is based on a composite reference signal containing all frequencies to be controlled. For tonal components that are close in frequency, a long FIR filter is required; this results in slow convergence of the adaptive algorithm.¹¹ For the parallel-filter structure, each frequency component is individually processed. This results in shorter filters and thus improved convergence performance.¹¹ Where possible, the parallel structure rather than the single-filter structure should thus be used to achieve efficient and robust control of frequencies that are close together. An example of

such a sound field is the beating sound produced by propellers rotating at slightly different speeds.

The well-known time-domain filtered-x least mean squares (FXLMS) algorithm^{7,11,16} may be generalized to multichannel control applications comprising the R single-frequency reference signals $x_r(n)$, $r \in \{1, \dots, R\}$, L control source signals $y_l(n)$, $l \in \{1, \dots, L\}$, and M error sensor signals $e_m(n)$, $m \in \{1, \dots, M\}$. Figure 4 shows a block diagram illustrating the feedforward control system based on parallel-filter structure and the multichannel FXLMS algorithm.

The leaky FXLMS algorithm is, however, usually used to steer the adaptive filter coefficients when solving practical control problems.^{11,16} Based on RL adaptive FIR filters and ML FIR filter control path estimates, the time-domain multichannel leaky FXLMS algorithm is given by^{11,16}

$$\begin{aligned} \mathbf{y}(n) &= \mathbf{X}^T(n) \mathbf{w}(n) \\ \mathbf{e}(n) &= \mathbf{d}(n) + \mathbf{y}_C(n) \\ \mathbf{w}(n+1) &= \gamma \mathbf{w}(n) - \mu \mathbf{X}_C^T(n) \mathbf{e}(n) \end{aligned} \quad (1)$$

where μ is the adaptation step size and γ is a real positive leakage factor in the range $0 < \gamma < 1$, $\mathbf{y}(n)$ is the output signal vector from the controller containing the L secondary actuator signals, and

$$\mathbf{w}(n) = [\mathbf{w}_1^T(n) \quad \dots \quad \mathbf{w}_L^T(n)]^T$$

is the vector containing the coefficients of the RL adaptive FIR filters. Each vector

$$\begin{aligned} \mathbf{w}_l(n) &= [w_{1l0}(n) \quad \dots \quad w_{1lJ-1}(n) \\ &\quad w_{2l0}(n) \quad \dots \quad w_{RlJ-1}(n)]^T \end{aligned}$$

Figure 4 Feedforward active control system based on the multichannel Filtered-X LMS algorithm.

is composed of the coefficients of the adaptive FIR filters controlling the secondary source l . Also

$$\mathbf{d}(n) = [d_1(n) \quad \dots \quad d_M(n)]^T$$

is the vector containing noise to be controlled at the error sensors,

$$\mathbf{e}(n) = [e_1(n) \quad \dots \quad e_M(n)]^T$$

is the residual vector containing the M residual signals, and

$$\mathbf{y}_C(n) = [y_{C_1}(n) \quad \dots \quad y_{C_M}(n)]^T$$

is the control sound vector, that is, $y_{C_m}(n)$ is the superposition of the contributions from the L secondary sources at error sensor m . The $RLJ \times L$ reference signal matrix $\mathbf{X}(n)$ is defined as

$$\mathbf{X}(n) = \text{diag}[\mathbf{x}(n) \quad \dots \quad \mathbf{x}(n)]$$

where

$$\mathbf{x}(n) = [\mathbf{x}_1^T(n) \quad \dots \quad \mathbf{x}_R^T(n)]^T$$

and

$$\mathbf{x}_r(n) = [x_r(n) \quad \dots \quad x_r(n - J + 1)]^T$$

denote FIR filter reference signal vectors. The length of the adaptive FIR filters is J . $\mathbf{X}_{\hat{C}}(n)$ is the $RLJ \times M$ filtered reference signal matrix, and the elements are produced by filtering the reference signals with FIR filter estimates of the physical paths between the secondary sources and the error sensors, that is, the control paths.

Differences between the estimate of the control paths and the true control paths influence both the stability properties and the convergence rate of the algorithm.^{11,16} To ensure convergence of the mean coefficient vector $E[\mathbf{w}(n)]$, the step size μ requires that $0 < \mu < (2(\Re\{\lambda_{lrj}\} + \alpha)/|\lambda_{lrj} + \alpha|^2)_{\min}$, where $\Re\{\cdot\}$ denotes the real part.^{11,16} Here, λ_{lrj} is an eigenvalue of the correlation matrix $E[\mathbf{X}_{\hat{C}}(n)\mathbf{X}_{\hat{C}}^T(n)]$, α is a real positive constant related to the leaky coefficient as $\gamma = 1 - \mu\alpha$ and $\mathbf{X}_C(n)$ is the filtered reference signal matrix produced by filtering the reference signals $x_r(n)$ with the actual control paths. Generally, the correlation matrix is ill-conditioned and has a large eigenvalue spread¹⁶; this usually results in a slow convergence speed, particularly when long adaptive FIR filters are used in the algorithm. The problems of an ill-conditioned correlation matrix and high computational complexity can be reduced by using frequency-domain versions of the multichannel FXLMS algorithm.

An alternative approach to the multichannel FIR-based control system for controlling tonal noise, for example, propeller-induced noise, is a system based on either complex arithmetic or a frequency-domain algorithm.^{11,16,19}

If each of the R complex reference signals, $x_r(n)$, may be separately controlled by an adaptive complex weight $w_{rl}(n)$, this results in the complex weight vector

$$\mathbf{w}_{rh}(n) = [w_{rh1}(n) \quad \dots \quad w_{rhL}(n)]^T$$

A low-complexity control algorithm based on the complex FXLMS algorithm for updating the weight can now be formulated in a matrix notation as^{11,19}

$$\mathbf{w}_r(n+1) = \gamma \mathbf{w}_r(n) - x_r^*(n) \mathbf{M}_r \hat{\mathbf{C}}_r^H \mathbf{e}(n) \quad (2)$$

where the superscripts $*$ and H denote the complex conjugate and conjugate-transpose, respectively, and γ is a real positive leakage factor. $\hat{\mathbf{C}}_r$ is an $M \times L$ matrix of estimated frequency responses \hat{C}_{rml} from the secondary source l to the error sensor m , and $\mathbf{e}(n) = [e_1(n), \dots, e_M(n)]^T$, that is, the real broadband error sensor signals. The $L \times L$ matrix \mathbf{M}_r is a convergence factor matrix containing spatially normalized convergence factors.^{12,15,20} This matrix affects convergence properties and system performance. Normalization is important for large multichannel applications where the acoustical coupling, that is, the magnitude of the frequency responses between different secondary sources and error sensors can vary.

The convergence factor matrix for the Newton-type algorithm is given by $\mathbf{M}_r = \mu_0[\rho_r \hat{\mathbf{C}}_r^H \hat{\mathbf{C}}_r]^{-1}$, where μ_0 is the step size parameter, $0 < \mu_0 < 1$, and ρ_r denotes the mean power of the reference signal $x_r(n)$.^{16,19} The signal power can be predetermined in the reference generator or estimated at run time, for example, by using the exponential average $\hat{\rho}_r(n) = \varepsilon |x_r(n)|^2 + (1 - \varepsilon)\hat{\rho}_r(n-1)$, $0 < \varepsilon < 1$.¹¹ In practical applications, normalization is also important to compensate for variations in the mean power of the reference signal. In the Newton-type algorithm, all frequency responses in the control configuration are used in the update of every adaptive weight. In control applications comprising a large number of secondary sources and error sensors, it can be assumed that acoustical coupling decreases as the distance between the sources and sensors increases. This results in a diagonally dominant matrix $\hat{\mathbf{C}}_r^H \hat{\mathbf{C}}_r \approx \text{diag}\{\hat{\mathbf{C}}_r^H \hat{\mathbf{C}}_r\}$, which in turn leads to the actuator-normalized algorithm.¹⁹ The convergence factor matrix for the algorithm—which is normalized for each actuator—is given by $\mathbf{M}_r = \mu_0[\rho_r \text{diag}\{\hat{\mathbf{C}}_r^H \hat{\mathbf{C}}_r\}]^{-1}$, $0 < \mu_0 < 1/RL$.¹⁹ Since the frequency responses $\hat{\mathbf{C}}_r$ are estimated before control takes place, quantities in the convergence factor matrix \mathbf{M}_r can be calculated before controlling,¹⁹ thereby significantly reducing the calculation burden during run time.

The real controller output signals are generated according to $\mathbf{y}(n) = \sum_{r=1}^R \text{Re}\{x_r(n)\mathbf{w}_r(n)\}$, where $\text{Re}\{\cdot\}$ denotes the real part. In the practical implementation only the real part of the product is evaluated. The complex LMS algorithm has properties that are superior to those of the FIR-based LMS algorithm when it comes to controlling harmonic sound fields with the aid of a multichannel control system. Some of the most interesting advantages include a simple controller structure, individually controlled harmonics, efficient algorithm normalization with high tracking performance, favorable implementation properties, and reduced calculation complexity.

3.5 Active Headsets and Quiet Seats

The feedforward control systems rely on the existence of some prior knowledge of the noise to be controlled.^{11,16} This knowledge is provided by reference signals, for example, from the engines. The

feedback control systems do not rely on reference signals.^{11,16} The basic principle acoustical feedback control is that the output signal of the error microphone is fed back to the control unit where it is processed and then used to drive the loudspeaker. The loudspeaker is located in the vicinity to the error sensor. The objective of the control system is principally to minimize the perceived sound pressure. Active headsets and quiet seats usually rely on feedback control.^{7,10,16} Headsets are normally of the analog type; quiet seats use digital control.^{7,14,16} Both active headsets and quiet seats deal with broadband noise.

The sound pressure under control, $p_e(f)$, is inside an active headset or on either side of the quiet seat headrest, and can be written as $p_e(f) = p_d(f)/[1 + W(f)C(f)]$ where $p_d(f)$ is the sound pressure inside the active headset or at the headrest without control, $W(f)$ is the frequency function of the controller, and $C(f)$ is the frequency function of the control path, that is, the transfer path comprising the loudspeaker, headset cavity, and error microphone. By allowing the loop gain $|W(f)C(f)|$ to assume large values, the magnitude of the denominator becomes large, and the sound pressure under control is reduced. In practice, however, the performance of an active feedback control system is limited by closed-loop stability requirements, that is, the Nyquist stability criterion.^{7,16} The electroacoustical response of the loudspeaker and the acoustical path from the loudspeaker to the microphone introduce time delay due to propagation time, and this will introduce increasing phase shift with frequency and thus limit the performance of the control system. The time delay can be reduced by bringing the error microphone closer to the loudspeaker. This in turn increases the operation bandwidth. Analog active noise control headsets typically produce an attenuation of about 20 dB at 100 to 200 Hz, which falls to zero below approximately 30 Hz and above approximately 1 kHz.¹⁷ Active noise control headsets can also be used as ordinary stereo headphones in combination with external electronics, for example, portable CD players, the aircraft entertainment system, or radio communication system used by pilots.

4 OPTIMIZATION OF SECONDARY SOURCES, ERROR SENSOR LOCATION, AND PERFORMANCE PREDICTION

The optimum arrangement of the control sources and error sensors depends upon whether the objective is to minimize the noise globally or minimize the noise locally.¹⁶ The control of an enclosed sound field requires spatial and temporal matching between the uncontrolled sound field and the sound field generated by the active noise control system.^{10,21} Temporal matching is maintained by the adaptive controller system, while spatial matching depends on the placement of the secondary sources and the error sensors. For an active noise control system to be effective, the secondary sources must be able to drive the sound field at all the desired frequencies; it is also important that the error sensors are able to observe the

controlled sound field properly.¹⁰ Accordingly, the secondary sources should be distributed in such a way that they couple effectively into the sound field, resulting in source positions close to the pressure maximum (antinodes) of the controlled acoustic modes. Similarly, the error microphones should also be distributed in such a way that their positions do not coincide with the pressure minimum (nodes) of the controlled acoustic modes.¹⁰ Generally speaking, one must conclude that positioning sources and error sensors at, or close to, nodal surfaces should be avoided. In complex geometric enclosures, for example, aircraft cabins, identifying the nodal surfaces for the dominant acoustic modes is a complex task, making it difficult to position the secondary sources and error sensors.^{10,16} Furthermore, the installation of the system is also limited by practical restrictions, for example, a loudspeaker requires a certain volume behind the speaker, a position can already be occupied by other cabin equipment, or the position is impractical for assembly and maintenance purposes. The loudspeakers and error microphones are often mounted in the interior trim of the aircraft, see Fig. 3. The objective of the control system is to minimize the sound pressure in the error microphones. In most practical applications it is not possible to place the error microphones exactly in the positions where the noise reduction is most desired, for example, in the headrests. For this reason, when one evaluates the performance of the active control system a set of *evaluation* microphones is placed in those positions where noise reduction is most desirable, for example, in positions near the ears of the passengers. These microphones are used for evaluation purposes only.^{4,22} The purpose of the positioning of the secondary sources and error sensors is to determine a source and sensor configuration that will result in the desired noise reduction at the M_e *evaluation* microphones. Furthermore, it is important to find a robust configuration that leads to a significant reduction in all frequencies of interest; one must also find a configuration that leads to a significant reduction over a range of flight conditions rather than one that is useful for one flight condition only.^{4,10} The source and sensor positioning procedure can be seen as a combinatorial optimization problem, that is, one selects the configuration \mathbf{s} consisting of L sources and M error sensors ($L > M$) from all the L_c conceivable source positions and the M_c conceivable error sensor positions.^{16,19,22} The total number of different system configurations possible is given by

$$N_{\text{tot}} = \binom{L_c}{L} \binom{M_c}{M} = \frac{L_c! M_c!}{(L_c - L)! L! (M_c - M)! M!} \quad (3)$$

where $L_c!$ denotes the L_c factorial, that is, $L_c(L_c - 1)(L_c - 2) \dots 1$.¹⁶ To compare the performance of different placements of the secondary sources and error sensors, it is necessary to assess the sound field at the *evaluation* microphones. The evaluation cost function, related to the frequency f , for a specific configuration \mathbf{s} chosen from the conceivable positions can be formed according to the sum

of the squared evaluation microphone output signals, $J_{e,f}(\mathbf{s}) = \mathbf{e}_{e,f}^H(\mathbf{s}) \mathbf{e}_{e,f}(\mathbf{s})$.^{16,19} However, the cost function can be extended using other cost terms, for example, the maximum level of the loudspeaker input signals or the mean power consumption of the complete active noise control system. Here, $\mathbf{e}_{e,f}(\mathbf{s}) = \mathbf{d}_{e,f} + \hat{\mathbf{F}}_{e,f}(\mathbf{s}) \mathbf{y}_{\text{opt},f}(\mathbf{s})$ where $\mathbf{d}_{e,f} = [d_{e1,f}, \dots, d_{eM_e,f}]^T$ is a complex vector of the uncontrolled sound field at the evaluation points, $\hat{\mathbf{F}}_{e,f}(\mathbf{s})$ forms an $M_e \times L$ matrix of the frequency responses $\hat{F}_{m_e,l,f}$ between the L chosen secondary sources and the M_e evaluation points, and $\mathbf{y}_{\text{opt},f}(\mathbf{s}) = [y_{\text{opt}1,f}, \dots, y_{\text{opt}L,f}]^T$ is the optimal driving signals from the secondary sources given by $\mathbf{y}_{\text{opt},f}(\mathbf{s}) = -[\hat{\mathbf{C}}_f^H(\mathbf{s}) \hat{\mathbf{C}}_f(\mathbf{s})]^{-1} \hat{\mathbf{C}}_f^H(\mathbf{s}) \mathbf{d}_f(\mathbf{s})$. The optimal driving signals for configuration \mathbf{s} are obtained by minimizing the controlled sound field in the *error* sensors, $\mathbf{e}_f(\mathbf{s}) = \mathbf{d}_f(\mathbf{s}) + \hat{\mathbf{C}}_f(\mathbf{s}) \mathbf{y}_f(\mathbf{s})$, in least-squares sense.¹⁶ Here, $\mathbf{d}_f(\mathbf{s}) = [d_{1,f}, \dots, d_{M,f}]^T$ is a complex vector of the uncontrolled sound field at the error sensors, and $\hat{\mathbf{C}}_f(\mathbf{s})$ denotes an $M \times L$ matrix of the frequency responses $\hat{C}_{m,l,f}$ between the chosen secondary sources and error sensors. The noise attenuation in decibels for a specific configuration at the frequency f can be assessed by $10 \log_{10} [\mathbf{d}_{e,f}^H \mathbf{d}_{e,f} / \mathbf{e}_{e,f}^H(\mathbf{s}) \mathbf{e}_{e,f}(\mathbf{s})]$.

Devising a practical system installation is a complex task that is often difficult and time consuming. As an example, let $L_c = 20$, $M_c = 30$, $L = 8$, and $M = 16$ (possible configuration for small turboprop aircraft), resulting in $N_{\text{tot}} \approx 1.8 \times 10^{13}$. Assume that the time consumption for evaluating the performance for a single configuration is approximately 1 ms, a total of 570 years is required to evaluate all possible configurations. Accordingly, an exhaustive search over all conceivable configurations is *not* possible; some kind of optimization technique must thus be applied to establish a configuration of the secondary sources and error sensors in a reasonable period of time.^{4,16} Depending on the aircraft type and size, the number of secondary sources and error sensors may vary, for example, a 50-seat Saab 2000 is equipped with 36 loudspeakers and 72 microphones, and the Q series Dash-8 has approximately 36 to 42 active tuned vibrations absorbers (ATVAs) and 71 to 80 microphones.^{4,12}

The cost as a function of secondary source and error sensor positions is nonconvex; standard gradient search methods are thus of no use since the gradient algorithms are unable to escape from local minima in the nonconvex cost function.¹⁶ A very simple approach to escape from local minima is random search; one selects at random a number of source and sensor configurations and hopes that a configuration with satisfactory noise attenuation will be found among these. This principle of selecting a configuration often results in unsatisfactory noise attenuation due to the limited number of configurations that can be evaluated in a reasonable period of time. A more sophisticated search algorithm must be applied to obtain higher noise reduction in a systematic manner. Powerful optimization methods for finding a suitable configuration in a reasonable time are the genetic search (GS) algorithms and the

simulated annealing (SA) algorithms.^{16,19} One advantage of these algorithms is the ability to escape from local minima in a nonconvex cost function. Both methods are inspired by nature: GS algorithms are based on the biological mechanisms of Darwin's theory of evolution,^{20,23} and SA algorithms are based on the fixation of the atoms in a substance during the annealing process, that is, the temperature is gradually reduced to obtain a low-energy, atomic arrangement.^{24,25} The SA algorithm is based on the Metropolis sampler.²⁶ It follows a number of iteration steps; these are briefly described below.^{16,19}

The first step is to select at random an initial configuration \mathbf{s}_i from the conceivable secondary source and error sensor positions; for each new iteration select a new configuration \mathbf{s}_j . If $J_{e,f}(\mathbf{s}_j) \leq J_{e,f}(\mathbf{s}_i)$ accept \mathbf{s}_j as the new configuration ($\mathbf{s}_i = \mathbf{s}_j$), or if $J_{e,f}(\mathbf{s}_j) > J_{e,f}(\mathbf{s}_i)$, accept \mathbf{s}_j as the new configuration with the probability $P(\mathbf{s}_i, \mathbf{s}_j) = \exp([J_{e,f}(\mathbf{s}_i) - J_{e,f}(\mathbf{s}_j)]/T)$, where T is a pseudotemperature. The algorithm will accept a configuration with a higher value on the cost function in accordance with a probability function; this in turn allows one to escape from local minima in the cost function. However, the probability of escaping from local minima decreases during the search process. The above iteration steps are performed for N iterations using a fixed pseudotemperature T_n ; the best configuration is subsequently stored. The temperature is then updated and further N iterations are performed. The temperature is updated according to $T_{n+1} = \alpha T_n$, $n \in \{0, 1, \dots, N_a - 1\}$, where the temperature is reduced by the cooling factor α , ($0 < \alpha < 1$), and where T_0 is the initial temperature. The search is terminated after N_a iterations, and the best configuration is then found among the stored configurations. New configurations are obtained by exchanging one or more loudspeakers and error microphones in the configuration. The exchange can take place at random or following some predetermined procedure. Optimization is carried out using different methods, for example, optimizing the sources first and then the sensors, or optimizing the sensors first, followed by the sources.^{16,19,22} By combining these methods, the source and sensor locations can be optimized alternately or simultaneously. However, experience shows that certain combined methods are preferable.¹⁹

CHAPTER 101

NOISE PREDICTION AND PREVENTION ON SHIPS

Raymond Fischer

Hanover, New Hampshire

1 INTRODUCTION

Ship noise prediction, reduction, and control are important factors in the performance of underwater acoustical systems and in the habitability of the vessel for the crew and passengers. Mammals can also be affected by a ship's radiated signature. One of the principal objectives of this chapter is to provide engineering procedures for estimating the source–transmission path–receiver acoustical relationships applicable to ships. For any vessel the major sources are the propulsion machinery and propulsors. The airborne and structure-borne transmission paths are equally important due to the low damping loss factors in typical ship constructions. The received level in the compartment or the ocean depends on how the vibrations of local structure couple to the adjacent fluid. Criteria, specification development, design guidance, and abatement techniques are provided to assist the engineer in achieving an optimal system.

2 CRITERIA

Ship noise as it relates to human factors is a critical issue in ship design and operations. For 1999, the hearing compensation claims paid to veterans totaled \$291.7 million, and for 2004 this number increased to \$633.8 million. U.S. Navy and Marine Corps payments were \$63.5 million in 1999 and \$158.4 million in 2004. This exponentially increasing toll on human hearing and medical cost is preventable by bringing together the work of the engineering, safety, and medical communities.^{1,2}

International, national, and local criteria exist for habitability noise, habitability vibration, and underwater radiated noise. Quoting from the International Maritime Organization (IMO) Resolution A.468 (XII) code for noise levels on ships,³ page 7 these criteria are intended to:

- Provide for safe working conditions by giving consideration to the need for speech communication and for hearing audible alarms. . .
- Provide the seafarer with an acceptable degree of comfort in rest, recreation and other spaces

and also provide conditions for recuperation from the effects of exposure to high noise levels.

The third purpose of habitability noise criterion is to protect or reduce noise-induced hearing loss. This code also addresses intermittent noise in addition to steady-state noise. High noise levels are expected to adversely impact speech intelligibility, sleep, and overall performance.

Per IMO, crew berths have an A-weighted noise criterion of 60 dB. The most stringent A-weighted cabin requirement typically invoked is as low as 45 dB. The U.S. Coast Guard^{3a} has noise requirements published in NVIC 12–82 (1982). Other regulatory guidelines exist for American Bureau of Shipping⁴—including ship and off-shore crews and passengers, Det Norske Veritas Comfort Class Rules,^{4a} and Lloyd's Register Provisional Rules—Passenger and Crew Accommodation and Comfort^{4b} (where noise and vibration limits are addressed).

The latest available Navy airborne noise criteria (OPNAVINST 9640.1A Shipboard Habitability Design Criteria Manual, 1996^{4c}) are given by the noise category designations defined below:

- *Category A:* Spaces where direct speech communication must be understood with minimal error and without need for repetition. Acceptable noise level is based on a talker–listener distance of either 3 or 12 ft. Category A-3 A-weighted limit 70 dB—applies when extreme talker-to-listener distance is less than 6 ft. Category A-12 A-weighted limit 60 dB—applies when the extreme talker-to-listener distance is 6 ft or greater.
- *Category B:* Spaces where comfort of personnel in their quarters is the primary consideration and communication considerations secondary—A-weighted limit 70 dB.
- *Category C:* Spaces where it is essential to maintain especially quiet conditions—A-weighted limit 65 dB.

- *Category D:* High-noise-level areas where voice communication is not important, ear protection is not provided, and prevention of hearing loss is the primary consideration—A-weighted limit 84 dB.
- *Category E:* High-noise-level areas where voice communication is at short distances and there is high vocal effort and where amplified speech and telephones are normally available—A-weighted limit 80 dB.

Other criterion addresses the far-field airborne signature of vessels to minimize impact on communities. This is especially true for ferries and harbor tugs. Underwater noise criteria are being developed to minimize the potential disturbance of ship noise on mammals—both with respect to their hearing and habitat.^{5,6}

There is a stringent underwater radiated criterion for vessels conducting fisheries research.⁷ For these noise critical ships it may be necessary to invoke noise and vibration limits on machinery. Various machinery vibration acceptance criteria also exist.^{8,9}

3 SPECIFICATION DEVELOPMENT

New or rehabilitated vessels should have a comprehensive acoustical section as part of the ship's specification. This specification should define the acoustical limits versus ship operational conditions, methods to be invoked for quality assurance and verification methods. The International Organization for Standardization (ISO) has developed standard ship measurement procedures.^{10,11} The limits—for both habitability and hearing conservation—may vary with the ship's operational conditions and should consider length of operation at that condition, for example, station keeping with the thrusters at full or partial power. The specification should define the extent of any noise control program (see Section 4). Verification testing, operating conditions, witnesses, and reporting requirements should be delineated.

To minimize confusion, avoid the mixed use of performance specifications and treatment (hardware) specifications. If the designer/builder is responsible for the acoustical environment, do not specify treatment approaches, other than minimum accepted treatments, if necessary. If treatments and noise control approaches are specified, do not impose a noise limit to be achieved. Often it will be beneficial to have a separate noise goal for heating, ventilation, air-conditioning (HVAC) equipment (dockside operation) and underway operation. As a minimum the HVAC noise goals should be 5 dB below the criterion when underway.

4 ACOUSTICAL CONTROL PLAN

The most successfully designed quiet ships have instituted a control plan. To the extent possible, the plan should define the owner's, designer's, and builder's roles and that of any acoustical subcontractor. The plan needs to address and provide information on administrative, management, and construction functions and

program schedules for integration of noise into the overall design. It should cover the planned acoustical goals, prediction methods, noise control treatment selection and optimization, review of drawings incorporating those designs, factory equipment testing, treatment construction inspections, and verification testing during dockside and underway trials.

5 ACOUSTICAL MODELING

Acoustical modeling for either habitability or radiated noise needs to account for:

- Source noise and vibration levels for critical equipment
- Noise transmitted over airborne, structure-borne, and secondary structure-borne paths (the later results from airborne noise impinging on the structure, which then transmits the noise along the structural path)—see Figure 1
- Noise radiating from the structure forming the compartment of interest
- Room acoustical characteristic of the receiver compartment (see Section 9.4)

For ships with powerful sources, varied construction materials, low damping, and distributed sources and receivers, this can be a formidable task. Diesels and propellers can produce high levels at low frequencies, thus octave band analyses between 31.5 and 8000 Hz are typically required to derive an accurate A-weighted noise level. Thus dozens of sources and hundreds of paths need to be accounted for on most vessels.

Comprehensive acoustical modeling documents are *Fundamentals of Ship Acoustics*¹² and *Design Guide for Shipboard Airborne Noise Control*¹³ and its *Supplement*,¹⁴ all available from the Society of Naval Architects and Marine Engineers (SNAME). Empirical methods tracing the “source–path–receiver” have

Figure 1 Source/path acoustical model.

been developed, but these are laborious and prone to error.^{13–15} The following sections provide a general review of this technique. With the advent of statistical energy analysis (SEA) an accurate accounting of the flow of energy can be made with three-dimensional acoustical models. These models significantly improve the accuracy over empirical methods. A hybrid SEA model whose algorithms consider the acoustical impact of many factors that are specific for ships—water loading of surfaces, finite sizes and orientation of mechanical sources in small compartments, hydrodynamic sources like propellers, thrusters, splash noise (for high-speed ships), the ship's HVAC noise, and on-deck sources—currently exist.^{16,17} With the advent of these types of programs and their quick turn-around time, trade-off studies and treatment optimization can be facilitated.

6 RADIATED NOISE

6.1 General Characteristics

In naval operations the noise radiated by a ship is a dominant source of information, that is, signal, for underwater sonar systems. Radiated noise from ships can be an important contributor to ocean ambient noise, as discussed in Chapter 48 of Ref. 18, and as a factor in oceanographic research and geophysical exploration and cruise ships operating in environmentally sensitive areas. Engineering estimates for noise predictions of specific classes of ship machinery are given in this chapter based on weight, power, and foundation types.

A singularly important text is *Mechanics of Underwater Noise*,¹⁹ which provides detailed information on both mechanical and hydrodynamical noise sources and radiation. Chapter 41 of Ref. 18 summarizes the physics of sound radiation from ship structures and illustrates the basic mechanisms with simple mathematical models. The effects of fluid loading on acoustic radiation of plates and cylindrical structures are described in Chapter 6. In addition, detailed descriptions of hydroacoustical noise sources, including propellers, cavitation, vortex shedding, and turbulent boundary layer flow-induced noise are covered in Chapter 45 of Ref. 18. These chapters provide valuable information directly related to the sources and characteristics of ship noise.

The five principal groups of radiated noise sources are (1) machinery vibration caused by propulsion

machinery and ships' services and auxiliary machinery, including steam, water, and hydraulic piping systems; (2) propellers, jets, and other forms of in-water propulsion; (3) acoustical noise within compartments below the waterline; (4) hydroacoustical noise generated external to the hull by flow interaction with appendages, cavities, and other discontinuities, and (5) fluid connected openings in the hull. A summary of these noise sources and their radiated noise characteristics is discussed in Ref. 20, from which Table 1 gives representative source levels as a function of frequency for a range of surface ships. The data for ships operating between 10 and 20 knots illustrate the dominance of low-frequency noise.

The speed/power dependence of the radiated underwater noise of surface ships is further illustrated by the measurements plotted in Fig. 2.¹⁹ The 9-knot noise spectrum is governed by machinery sources while the significant increase in low-frequency noise as speed is increased is due to both propulsion machinery and the inception and development of propeller cavitation noise. The latter source of radiated noise is dealt with in Section 7. Ross¹⁹ provides estimation formulas for broadband underwater source levels, L_s , as a function of size or displacement tonnage and speed or power, for example,

$$L_s = 134 + 60 \log[U_a/(10 \text{ knots})] + 9 \log T_D \quad (1)$$

Figure 2 Radiated underwater noise levels of passenger ship *Astrid*, U.S. Office of Scientific R&D, published 1960.¹⁹ (From Ref. 18, Chapter 46, Fig. 1.)

Table 1 Representative Ship-Radiated Underwater Noise Levels Measured at 1 m from Center of Hull Side

Ship Class	Source Underwater Sound Pressure Levels re 1 μ Pa 1-Hz Bands (dB)						
	0.1 kHz	0.3 kHz	1.0 kHz	3.0 kHz	5.0 kHz	10.0 kHz	25.0 kHz
Freighter, 10 knots	152	142	131	121	117	111	103
Passenger, 15 knots	162	152	141	131	127	121	113
Battleship, 20 knots	176	166	155	145	141	135	127
Cruiser, 20 knots	169	159	148	138	134	128	120
Destroyer, 20 knots	163	153	142	132	128	122	114

Source: From Ref. 18, Chapter 46.

where U_a is ship speed in knots and T_D is displacement tonnage. Ross states that this formula is applicable for frequencies above 100 Hz and ships weighing under 30,000 tons. The acoustical efficiencies of ships have been found to range from 0.3 to 5 W of acoustic power for ship mechanical propulsion power of 1 MW; Ross suggests acoustical conversion efficiencies of 1×10^{-6} for machinery sources and 1.5×10^{-6} for cavitating propellers.

6.2 Noise Spectra

Noise spectra are generally classified in two types: (a) broadband noise having a continuous spectrum such as that associated with cavitation and (b) tonal noise containing discrete frequency or line components related to machinery, gears, propeller blade passage rate, and modulation of broadband noise. In addition to steady-state noise, ship noise is also characterized by transient and intermittent noise caused by impacts, loose equipment or rudders, or unsteady flow that have particular spectral properties. Ship noise is generally a combination of continuous and tonal noise covering the audio spectrum and is usually concentrated in the low-frequency region. Figure 3 shows a diagrammatic comparison of two radiated noise spectra in which auxiliary machinery tonal noise governs the low-speed condition, and propulsion system speed-related frequencies are superimposed on broadband propeller cavitation noise at high speeds. Figure 4 gives an overview of the frequency range of the major sources of radiated noise and shows that the majority of machinery sources produce noise from 10 to 1000 Hz, and significant sources such as cavitation and turbine lines may extend into the 10-kHz region and above.²¹

6.3 Machinery Noise

The principal mechanisms that generate vibratory forces involve mechanical unbalance, electromagnetic force fluctuations, impact, friction, and pressure fluctuations. The classes of machinery that produce noise may be categorized according to their functions, such as (a) propulsion machinery (diesel engines, steam turbines, gas turbines, main motors, reduction gears, etc.) and (b) auxiliary machinery (pumps, compressors, generators, air-conditioning equipment, hydraulic control systems, etc.).

Figure 5 is a schematic view of the machinery components of a diesel-electric propulsion system and their associated noise sources, which are described as follows:

1. Piston slap, which is a dominant noise mechanism of diesel engines and is caused by the impact of a piston against the cylinder wall, results in a spectrum made up of a large family of harmonically spaced tonals.
2. Mechanical imbalances of the generator and auxiliary machinery result in fluctuating forces and moments that are proportional to the square of the angular speed. Since the force is proportional to vibration velocity, the radiated power

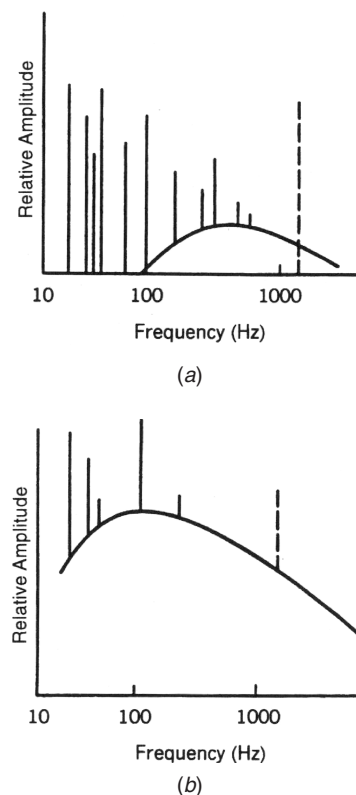

Figure 3 Diagrammatic spectra of submarine underwater noise at (a) low and (b) high speeds.²⁰ (From Ref. 18, Chapter 46, Fig. 2.)

increases as the fourth power of rotational speed.

3. Electromagnetic force fluctuations of the main drive motor are related to changes in the flux density, which are a function of the number of poles and result in low-frequency line spectra.
4. Reduction gear noise is dominated by gear tooth impacts and results in tones at multiples of the tooth contact frequency. Helical gears are significantly quieter than spur gears.
5. Propeller noise, which is discussed in Section 7, consists of two major components: (a) direct radiation from the propeller blades and (b) low-frequency hull vibration modes induced by hydrodynamic fluctuating forces acting on the blades and transmitted through the propeller shaft and thrust bearings to the hull. The hull response is thus related to the shaft rpm revolutions/minute and the number of propeller blades. The modes of hull vibration and resulting sound radiation are discussed in Chapter 41 of Ref. 18.

Figure 4 Frequency ranges of noise radiated by ship noise sources.²¹ (From Ref. 18, Chapter 46, Fig. 3.)

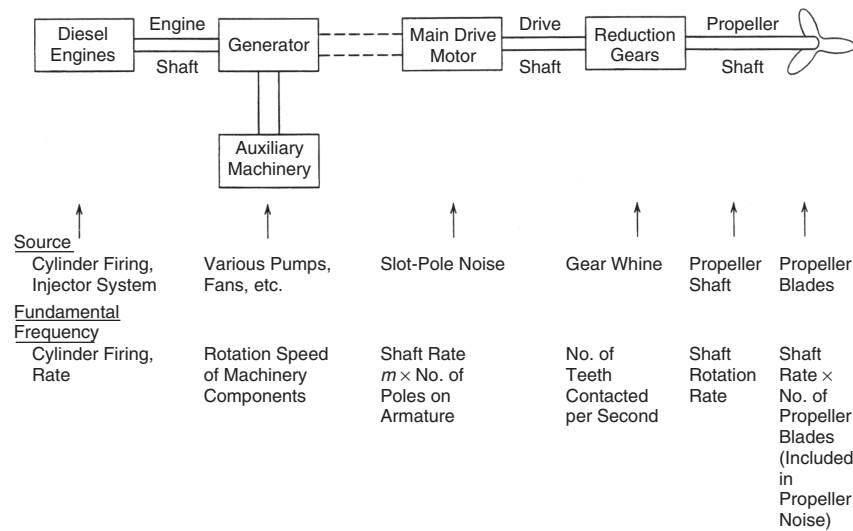

Figure 5 Machinery components and noise sources on a diesel-electric ship.²⁰ (From Ref. 18, Chapter 46, Fig. 4.)

6.4 Machinery Vibration Levels

The prediction of radiated noise from machinery sources is based on the traditional noise model, which involves vibration levels measured on the feet of machinery sources, transmission path dynamics including vibration isolation and foundation transfer functions, and hull vibration and radiation. The role of foundation structural mobilities is a critical part of this system and directly determines the vibration levels of the source machinery, as discussed in Chapter 71 of Ref. 18. The purpose of this section is to

provide engineering estimates for machinery vibration levels, based on an extensive database, as an input to structural design and noise radiation calculations developed for SNAME.^{13,14}

The source level algorithms are provided for engineering guidance. Reliable measured data should be used when available. Also, the parametric dependencies of the prediction algorithms can be used to scale from measured data for similar classes of machinery. It should be noted that the source vibration levels assume that the machine is mounted on

low-frequency vibration isolation mounts. Thus the effect of rigid mounting is to decrease machinery source vibration levels due to the increased constraining effect of the foundation relative to that of resilient mounts.

Table 2 gives source vibration velocity levels in decibels relative to 10^{-6} cm/s as a function of octave bands for two types of gas turbines and for representative classes of electric motors. Table 3 gives formulas for overall machinery source vibration levels expressed as baseline vibration velocity in decibels relative to 10^{-6} cm/s. The machinery parameters

include w = gross weight in kilograms, kW = rated power in kilowatts, and actual and rated rpm. The types of machinery include diesels, generators, pumps, and reduction gears. For each type, adjustments to the overall levels are given in Table 4 to obtain estimates of vibration levels for the designated octave bands. Alternative prediction procedures may be found in other handbooks.^{15,22-24}

6.5 Structural Vibration Transfer Functions

The effects of the transmission of vibratory energy (structure-borne noise) along and through different structural paths are expressed as transfer functions that

Table 2 Baseline Octave Band Vibration Levels Measured on Feet of Machinery Sources

Machinery Type	Baseline Vibration Levels, L_{VB} (dB re 10^{-6} cm/s)										
	Octave Band Center Frequency										
	16 Hz	31.5 Hz	63 Hz	125 Hz	250 Hz	500 Hz	1 kHz	2 kHz	4 kHz	8 kHz	16 kHz
Gas turbines											
Small high speed	80	85	95	100	100	90	110	100	100	95	95

Source: From Ref. 18, Chapter 46.

relate the input (machinery) and output (foundation or hull) vibration levels. In this section an empirical procedure is given for estimating transfer functions for different transmission paths. The U.S. Navy has published several design handbooks to guide structural designers.^{25–28} It should be noted that state-of-the-art PC-based noise models can provide greatly refined and more accurate transfer function estimates for specified structural configurations, and the accompanying estimates should only be used for guidance. Furthermore, multiple vibration transmission paths must generally be considered for ship noise predictions.

Vibration Isolation Mountings The transfer function or transmission loss is expressed as the log ratio of vibration velocity above the mounts at the attachment to the machine subbase to that on the foundation structure below the mounting system. In this design guide, sources of vibration are divided into three weight classes: class I, less than 450 kg; class II, 450 kg to 4500 kg; and class III, over 4500 kg.

Table 5 gives representative transmission loss values for four types of mounting configurations: hard mounted (no vibration isolation), distributed isolation material (DIM), single-stage low-frequency isolation mounts, and two-stage isolation with intermediate rafts. The estimates are presented as average values for the designated octave bands. For the hard-mounted case lightweight machines can be expected to have a modest loss at low frequencies, while all classes of machinery have little or no loss above 250 Hz. The DIM installations are effective for lightweight machines above 250 Hz, but their performance decreases as the machinery weight increases.

The losses of low-frequency mounts closely follow theoretical predictions for lightweight machines, that is, 20 dB to 30 dB transmission loss over the given frequency range. However, as the weight of a machine increases relative to that of the foundation structure, the degree of isolation decreases, reflecting the overall impedance relationships. Two-stage mounting systems have been implemented extensively in ship designs and have proved to be highly effective, assuming potential airborne flanking paths are considered (see Section 9.5). Double-stage isolation mounts have been used successfully for diesel generators on at least eight fisheries research vessels built to the International Council for the Exploration of the Sea (ICES) radiated noise standards.⁷

6.6 Hull Vibration-Radiated Underwater Noise

The relationships between hull structural vibration levels and radiated noise are discussed in Chapter 6 of this handbook and Chapter 41 of Ref. 18. Assuming that the radiation efficiency σ_r is known, a first-order estimate of the sound radiated from hull plating can be calculated by¹³

$$L_s = L_v + 10 \log \sigma_r + 10 \log A_p + 10 \log n + 73 \quad (2)$$

where L_s is the equivalent source underwater sound pressure level at 1 m, L_v is the space average vibration velocity level of the hull plating, A_p is the area of a single hull plate in square metres and n is the number of radiating panels.

Table 5 Representative Transmission Loss Values versus Octave Band Center Frequency for Ship Machine Mounting Arrangements (dB)

Machinery Weight Class ^a	Transmission Loss, dB								
	Center Frequency								
	31.5 Hz	63 Hz	125 Hz	250 Hz	500 Hz	1000 Hz	2000 Hz	4000 Hz	8000 Hz
<i>Hand Mounted</i>

6.7 Hull Vibration Transmission

Hull vibration (calculated or measured) in the area of machinery foundation attachment locations (e.g., deep frames) is transmitted through the steel hull structure. Thus, larger areas of the hull may contribute to radiated noise. Also, the transmission of machinery excited hull vibration into sonar array structures can contribute to sonar self-noise (see Section 8). A useful guideline for broadband transmission loss in typical damped ship structures is 0.15 to 0.25 dB/m for cases of free-layer damping and 0.5 dB/m for structures, including wetted hulls, with constrained layer damping. Structural details are needed to establish frequency dependence.

6.8 Hull Grazing Sound Transmission Loss

Table 6 provides frequency-dependent expressions of propagation losses for sound traveling in the water along the length of the hull, which is grazing sound. The hull is considered to be an air-backed baffle, and the grazing sound transmission loss applies to a 1-m source level for far-field radiation. The theoretical basis for these estimates involves energy transmission through both the hull structure and the water path.

7 PROPELLER NOISE

7.1 General Characteristics

Propulsion propellers constitute a major source of underwater ship noise and, similar to fans, aircraft turboprops, helicopters, and other devices with rotating blades operating in nonuniform flow fields, are the subject of continuing noise control efforts. The interaction of blade forms and hydrodynamic flows and the resulting dynamic response of the blades and the associated acoustic radiation are complex phenomena that depend on a wide range of design and operational variables that do not lend themselves to simple models and noise predictions. Hydrodynamic noise sources are discussed in Chapter 45 of Ref. 18; in particular, Section 3 in that chapter provides the theoretical background for cavitation inception, development, and associated noise.

The guidelines for estimating propeller noise included in this chapter are based on the original work of Ross¹⁹ and the more recent engineering analyses presented in the report of the Nordic cooperative

project.²³ Waterjet and bow thrusters are also important sources for both internal and external noise. Noise and vibration levels and design guidance for minimizing bow thruster noise is provided in Ref. 29. Marine propeller noise reduction has benefited from parallel aerodynamic acoustical studies, which are the subject of other chapters in this handbook. For example, significant reductions in both propeller and fan noise have been achieved through smoothing and control of inlet flows and the design of skewed blades.

7.2 Propeller Noncavitating Underwater Noise

There are generally two to three components in the spectrum of a noncavitating propeller: (a) blade tonals related to propeller shaft speed and the number of blades; (b) propeller broadband noise related to blade vibratory response to turbulence ingestion and trailing-edge vortices; and/or (c) propeller singing due to coincidence of vortex shedding and blade resonant frequencies. Blade tonals and harmonics result from oscillating components of forces or propeller thrust variations caused by circumferential variations of the wake inflow velocity. Figure 6 illustrates, by use of equivelocity contours, the velocity variations in the plane of a single-propeller merchant ship. The flow speed varies from 10 to 90% of the forward speed of the propeller. These velocity differences cause large variations of the angle of attack and associated lift forces, which lead to significant fluctuations in thrust and torque during each revolution of the shaft and, in turn, to high-level, low-frequency hull vibration. Thus, the most important design consideration is the relationship between the harmonic structure of the wake and the number and blade form of the propellers.

The primary propeller design factors include diameter, shaft rpm, number of blades, expanded area ratio,

Figure 6 Wake diagram for a single-screw merchant ship.¹⁹ (From Ref. 18, Chapter 46, Fig. 5.)

Figure 7 Cavitation pressure pulses from collapsing cavity and idealized spectrum of sound pressure level.¹⁹ (From Ref. 18, Chapter 46, Fig. 6.)

blade load distribution, skew distribution, blade tip-hull clearance, and the spatial and temporal characteristics of the inflow field (see Ref. 30).

7.3 Propeller Cavitation Noise

As stated above, a description of cavitation is provided in Chapter 45 of Ref. 18. There are four types of propeller cavitation: driving face, suction face, tip vortex, and hub vortex. The blade tip speed governs cavitation inception, as shown in Eq. (14) of that chapter. Broadband cavitation noise results from the growth and collapse of a sheet of bubbles occupying a volume on the individual blades. Figure 7 illustrates this process for a single cavitation bubble with the resultant idealized spectrum. The general noise spectrum of blade cavitation is shown in Fig. 8 and has four principal spectral regions:

- I. Low frequency: contains blade frequency ω and harmonics; mean power level increases as ω^4 .
- II. Midfrequency: starts at bubble frequency ω_b ; mean power level increases as $\omega^{-5/2}$.
- III. Intermediate frequency: transition region between regions II and IV.
- IV. High frequency: starts at bubble frequency ω_c ; mean power level decreases as ω^{-2} .

In regions I and II the fluctuations of the sheet cavitation volumes may be represented by a large bubble that acts as an acoustic monopole. In region

Figure 8 General noise spectrum level of a cavitating propeller.²³ (From Ref. 18, Chapter 46, Fig. 7.)

IV, the power is caused by cavity collapse or by shock wave generation by nonlinear wave propagation. Region III contains a mixture of regions II and IV. Figure 9 is an example of a comparison between predicted and full-scale measured source levels for a 32,000-ton vessel.^{18,23}

8 PLATFORM AND SONAR SELF-NOISE

8.1 General Characteristics

Conceptually, self-noise is that noise in a sonar system attributable to the presence of the platform, as illustrated in Fig. 10. In practice, sonar self-noise measurements always include the contribution of the ambient noise. The self-noise term in the sonar equation set forth in Chapter 49 of Ref. 18 is also all inclusive. Thus, sonar self-noise is really the total noise level of a sonar when there is no target present.

Two kinds of self-noise measurements are made: *platform noise* measurements are self-noise measurements made with omnidirectional hydrophones; *sonar self-noise* measurements are made at the output of the designated array. Platform noise is L_N in the sonar equation, while sonar self-noise L_e is the equivalent of $L_N - N_{DI}$, where N_{DI} is the measured array gain. It is important to measure the sonar self-noise directly because the array signal-to-noise gain depends upon the spatial properties of the noise field. The directivity index, which is based on isotropic noise, is a first-order approximation of the ability of an array to discriminate against noise, but it usually does not equal the actual array gain. In fact, coherent noise sources can appear as target signals on sonar displays.

In treating sonar self-noise, it is convenient to consider six dominant noise sources:

1. Ambient ocean noise
2. Local machinery sources
3. Remote machinery sources
4. Propeller noise
5. Local flow noise
6. Local cavitation and/or bubble sweepdown

Figure 9 Comparison between predicted and measured noise levels.²³ (From Ref. 18, Chapter 46, Fig. 8.)

Figure 10 Primary sources of self-noise.²¹ (From Ref. 18, Chapter 46, Fig. 9.)

Ambient noise is discussed in Chapter 47 of Ref. 18. It generally dominates only at slow speeds. Figure 11 illustrates how at low sea states (e.g., sea state $\frac{1}{2}$) ambient noise may control sonar self-noise only at low ship speeds before other speed-dependent noise sources begin to dominate. At sea state 3, ambient noise controls sonar self-noise up to higher ship speeds.

At the other extreme, *local cavitation* on the sonar dome is generally a problem only at the highest speeds of surface ships. In moderate to high sea states,

bow wave splash is a significant noise source that extends along the line of the breaking bow wave. It is highly dependent on ship motion with respect to the seaway. Machinery can contribute noise into the sonar arrays by vibrational paths, and these sources may be significant over a wide speed range. Propeller noise may be transmitted to sonar arrays by hull vibration, hull grazing (see Table 6), and by surface-reflected paths. Small water area twin hull (SWATHs) may also have a "cross-hull" path. Each type of noise source has individual speed and power dependencies

Figure 11 Speed-dependent self-noise as a function of sea state, relative sonar noise level vs. speed, knots.¹⁹ (From Ref. 18, Chapter 46, Fig. 10.)

that contribute in varying degrees to the overall sonar self-noise level as a function of speed.

At higher speeds *local flow noise* is a dominant noise source. The mechanisms whereby turbulent boundary layer pressure fluctuations excite flush-mounted hydrophones, sonar domes, and structures local to the sonar are discussed in Chapter 45 of Ref. 18. The wavenumber of the convective turbulent excitation is much larger than that of the acoustical signal of the same frequency. It is thus possible to design hydrophones and arrays to discriminate against flow noise while maximizing signal gain.

The importance of remote machinery and propellers as contributors to self-noise is apparent when close correlations between radiated noise and sonar self-noise are recognized. The two principal paths are surface boundary reflection or scattering and hull vibration. Hull vibration is particularly important for low-frequency noise while the acoustical path surface ship sonar self-noise is often higher in shallow water than in deep water. Generally speaking, the reduction of radiated noise can also be important to improving sonar performance.

8.2 Dome Design

The term *dome* refers to a vaulted structure. It probably originated when rounded projections were first installed to protect protruding hydrophones. Today the term encompasses any structure housing arrays or hydrophones, whatever the shape, and sometimes even describes the supporting structure and array. Domes may now comprise the whole front portion of a submarine or the bulbous bow of a surface ship. They are either conformal domes (i.e., conforming to the general shape of the ship) or appendage domes (i.e., protruding into the water flow around the ship, as illustrated in Fig. 12).

The structural and acoustical factors involved in dome design and ship installations are dealt with in Ref. 31 and illustrated in Fig. 13. The acoustical factors in dome design, which are numbered

Figure 12 Sonar dome schematic. (From Ref. 18, Chapter 46, Fig. 11.)

in Fig. 13, are (1) transmission through material, (2) compressional and flexural coincidence angles, (3) flow excitation, (4) refraction, (5) internal reflection, (6) structure-borne noise, (7) waterborne noise, (8) reverberation, (9) cavitation, (10) bubbles, and (11) fouling.

When designing and installing sonar domes, the emphasis is on protecting the transducers, minimizing ship impact, and enhancing signal-to-noise ratio. The interposition of the dome, or window, reduces the signal level and, therefore, low-transmission-loss structures and materials are mandatory. At low frequencies, where large arrays and domes are required, the wavelengths are large and attenuation through the material is low. The thicker windows required for mechanical strength do not, therefore, cause unacceptable attenuation losses at these frequencies. Thus, design becomes a compromise between acoustic, hydrodynamic, and structural requirements and the location, size, operating frequency, and shape of the array.

Figure 13 Acoustical considerations in dome design. (From Ref. 18, Chapter 46, Fig. 12.)

Table 7 Hull-Mounted Sonar Array Baffle Diffraction Loss versus Frequency (dB)

Type of Barrier/Baffle	Diffraction Loss (dB)					
	250 Hz	500 Hz	1000 Hz	2000 Hz	4000 Hz	8000 Hz
Water backed	0	0	0	5	5	5
Air backed	8	11	14	17	20	23

Source: From Ref. 18, Chapter 46.

The dome or window should be made of tough, hard-to-damage, material because hydroelastic excitation or flutter around a damaged portion can cause noise. It can also be excited by the flow of water past its surface and radiated to the hydrophone if it is constructed of an elastic material (e.g., steel or fiberglass). A highly damped, low-modulus material such as rubber reduces flow noise problems. But in every case, it is important to maintain both the fairness and smoothness of the dome and the adjacent hull surfaces. Step discontinuities must be avoided.

The fluid inside the dome may become warmer than the surrounding sea and, thus, may not have the same speed of sound as the external water. This results in refractions and focusing, which leads to degradation in beam former performance and gives erroneous bearings. Thus dome design should provide for flushing and replacement of the internal dome water.

The dome is usually equipped with baffles aft of the array to reduce the effect of ship machinery and propeller noise on the sonar array. However, these baffles can also mask targets in the stem sectors. Flat or curved surfaces inside the dome can reflect incoming signals, and nonreflecting surface materials may be needed to reduce the possibility of spurious signals appearing in the array output. Table 7 gives values for diffraction losses as a function of frequency for typical water and air-backed sonar baffles.

8.3 Flow-Induced Noise

Turbulence is generated along the hull of a ship as it passes through the water. The fluctuating pressures associated with a turbulent boundary layer radiate noise directly into the water (flow noise) and excite vibrations in ship structures because the mechanism of direct radiation of flow noise into the water is inefficient. Flow noise is usually not a significant source of ship noise. However, flow-induced noise transmitted through excitation and radiation of sonar domes and adjacent hull structures becomes a significant source of sonar self-noise at higher speeds. Chapter 5 of this handbook and Chapter 45 of Ref. 18 provide more detailed information on hydroacoustic noise and structure-fluid interactions.

The estimates of platform self-noise given below are sound pressure levels at individual element locations within sonar domes. For flow-induced noise, platform noise levels inside the sonar domes are estimated by adding the values given below to the baseline level,

L_N (see Ref. 32):

$$L_N = 34 + 45 \log(V) - 20 \log(h) + 10 \log(A) \quad (3)$$

where V is ship speed in knots, h is the thickness of the sonar dome in centimetres, and A is the surface area of the sonar dome in square metres.

Octave Band Adjustments in Decibels (Add to L_N)

Center frequency (Hz)	31.5	63	125	250	500	1000	2000	4000	8000
Flow noise	39	28	19	16	13	10	7	4	1

9 INTERIOR COMPARTMENT NOISE

9.1 General Characteristics

The airborne noise levels in ships constitute a major area of ship acoustics. The high airborne noise levels of propulsion machinery and reduction gears in confined machinery spaces constitute a serious hearing and communication problem.

9.2 Airborne Sound Pressure Levels of Sources

The acoustic source levels of representative machinery noise sources in ships are expressed as sound power levels in octave bands with adjustments given in Table 8.^{13,14,32} Additional sources, such as exhaust pipe vibration and wave impact noise are considered in the *Supplement*¹⁴ to the original *SNAME Design Guide*.¹³ The *Supplement*¹⁴ also contains Excel spreadsheets that provide source noise and vibration levels for many marine sources, material absorption, and transmission loss values, as well as measured isolation mount performance characteristics.

1. Diesel engines intake, exhaust and casing radiation, baseline;

$$L_{WB} = 58 + \log(kW) \quad \text{dB re } 10^{-12} \text{ W} \quad (4)$$

2. Gas turbines, intermediate exhaust;

$$L_{WB} = 74 + \log(kW) \quad \text{dB re } 10^{-12} \text{ W} \quad (5)$$

Often machinery vendors only measure sound pressure levels at 1m and do not provide sound power levels (which would be independent of the acoustical

Table 8 Machinery Noise: Source Sound Power Levels (dB re 10⁻¹² W) Octave Band Adjustments

Machinery Class	Source Sound Power Levels (dB re 10 ⁻¹² W)

room environment in which they are measured). For a finite size source, the following method can be used to convert from the vendor-supplied data at a set distance to sound power levels or to the sound pressure level for another distance from the source.

The estimated sound power level, for equipment with dimensions L , B , H , in metres, may be found in accordance with the formula (independent of frequency)¹⁴

$$L_W = L_p(r_0) + 10 \log[12r_0^2 + 4r_0(L + B + 2H) + 2H(L + B) + LB] \quad (6)$$

where L is the machinery length, B is the width ($B < L$), and H is the height. In this formula, r_0 is the average distance between the equipment surface and the point where the noise levels were measured and L_p is the sound pressure level measured at a distance r_0 .

The direct field sound pressure level at some arbitrary distance r from the casing is equal to^{14,34}

$$L_p(r) = L_p(r_0) - 20\xi(\varphi) \log\left(\frac{r}{r_0}\right) + 10 \log[Q] - 1 \text{ dB} \quad (7)$$

where $L_p(r_0)$ is sound pressure level at distance r_0 from the machinery casing, $\xi(\varphi)$ is a function of the source shape and direction from the center of the source to the point of interest, and Q is the source directivity, and where $Q = 1$ for a source in the middle of the room, and $Q = 2$ for a source in a corner. Values of $\xi(\varphi)$ range between 0.15 and 0.9. Its value also depends on the angle between the equipment's longitudinal axis and direction to the point of interest in the machinery room.¹⁴ $\xi(\varphi)$ is lowest for high values of $L/\sqrt{(BH)}$.

9.3 Acoustic Transmission Path

Noise control measures in ships are similar to those in other architectural acoustic applications. An extensive and broad base of materials technology has been

developed and applied by the U.S. Navy and industry to meet surface ship and submarine habitability and environmental requirements. This technology is largely available to nonmilitary ship designers. A general noise model is given in Fig. 14. In addition, statistical energy analysis noise models are available to support alternative designs for noise control treatment combinations.

Examples of available noise control technology are as follows:

1. Internal high-transmission-loss "sandwich"-type composite treatments (e.g., fiberglass blanket/loaded vinyl septum/fiberglass blanket) or tuned double-wall constructions for reduction of airborne noise transmission through the hull or through partitions between compartments
2. Internal sound absorption materials for installation on bulkheads and overheads of ship compartments to reduce individual compartment noise levels
3. Vibration damping materials for application to internal ship structures to reduce transmission of structure-borne noise to interior compartments

Transmission loss data on a representative sample of commercial products that meet U.S. Navy requirements are given in Table 9.³⁵

9.4 Acoustic Absorption Materials — Room Constants

There are two classes of acoustical materials for sound absorption applications in (1) "clean" spaces and (2) machinery and equipment spaces and a third class to supplement structural transmission loss of decks, bulkheads, and interior joiner work.

Type I treatments are simply designed to reduce the reverberant sound field by increasing the sound absorption characteristics of interior bulkheads and overheads. Typically, 50mm-thick fiberglass blankets with perforated facings are used for this purpose. Such treatments typically provide on the order of 5 dB noise reduction in the A-weighted noise.

Figure 14 General noise model for ship systems airborne noise control. (From Ref. 18, Chapter 46, Fig. 13.)

Type II treatments are similar in function to type I treatments but generally consist of a 50-mm layer of fibrous glass material faced with an impervious fabric for protection and to reduce the risk of degradation in absorption characteristics due to oil and water contamination. However, the facing material generally degrades the absorption performance of the overall treatment.

Type III treatments are designed to supplement the transmission loss afforded by baseline structural decks and bulkheads and interior joiner work. Typically, these treatments incorporate relatively high density fiberglass installed as two separate blankets separated by a thin septum of lead-loaded or barium-sulfate-loaded vinyl. The outer, exposed layer of fibrous glass material can have either a perforated facing to maximize sound absorption or a thin facing impervious to oil and water. Table 10 provides data on ship acoustical materials.³²

The relationship between the received sound pressure level in a compartment and the acoustic power

radiated into the compartment is determined by³⁶

$$L_p = L_w - 10 \log([Q/(4\pi r^2) + (R/4)]) \quad (8)$$

where L_p is the received sound pressure level in dB re 20 μ Pa, L_w is the acoustic power level in dB re 1 pW, Q is the directivity factor of the source, r is the distance from the source to the receiver in metres, and R is the room constant in square metres. The room constant depends on many factors, including³⁷

$$R = S_{\text{total wall}} \left[10^{-(TL_{\text{wall}}/10)} + \left(\frac{4\pi\sqrt{12}\rho c^3\sigma}{c_L t \rho_s \omega^2} \right) \times \left(\frac{\rho_s \omega \eta}{\rho_s \omega \eta + 2\rho c \sigma} \right) \right] + \sum_i S_{gi} \alpha_{gi} + \sum_i S_{gi} 10^{-(TL_{gi}/10)} + \sum_i S_i \alpha_i \quad (9)$$

Table 9 Transmission Loss for Representative Ship Structure and Materials^a

Material No.	Panel Description, Type, and Thickness	Transmission Loss (dB)

Source: From Ref. 18, Chapter 46, Table 11.

where the last term is the boundary surface room constant and the first term accounts for room compliance and wall transmission loss. This equation varies with frequency. The first term is insignificant above 250 Hz. The following definitions apply:

$S_{\text{totalwall}}$ is total area of all boundary surfaces in the compartment of interest.

TL_{wall} is the average sound transmission loss of the compartment's boundary, including the structure and attachments such as joiner panels or insulation.

ρ is the density of air, 1.21 kg/m³.

ρ_s is the average mass per unit area of the boundary surface, kg/m².

ω is $2\pi f$, where f is the octave band center frequency.

η is the loss factor of a typical boundary surface, see the Design Guide¹³ and Supplement¹⁴ for values.

σ is the average radiation efficiency of a typical panel (between frames).

c_L is the longitudinal wave speed of the plate material, 5200 m/s in steel and aluminum.

t is the plate thickness, m.

S_g is the area of the i th gaps or openings (including duct terminals and door louvers), m².

TL_g is the transmission loss of the i th opening or gap (typically 0 to 5 dB); it can be computed

as $TL_g = 20 \log\{(t + 1.6a_g)/(a_g\sqrt{2})\}$, where a_g^* is the equivalent radius of the hole or gap and $a_g < \lambda = (c/f)^\dagger$; for a large gap (greater than 10% of the wall) the composite transmission loss should be computed per Eq. 7–15 of the Design Guide,¹⁴ and this value used in the computation of TL_{wall} and the term containing TL_g in Eq. (9) set to zero. To be conservative a TL_g value of zero can be used for gaps.

α_g is the absorption of the i th opening or gap (typically 0.5 to 0.99); for small holes this value can be computed as

$$\alpha_g = 10^{TL_g/10}$$

for a large gap, $a_g > \lambda$ use a value, $\alpha_g > 0.5$.

α_i is the absorption coefficient of the i th room boundary surface.

S_i is the surface area of the i th room boundary surface, ft² or m²

9.5 Airborne-to-Structure-Borne Paths

When there is isolation-mounted equipment, particularly double-stage mounts, the secondary structure-borne path can become important. Sound incident on the compartment's boundaries induces vibration in the structure. For bare exposed steel plating, secondary structure-borne vibration levels are computed for the frequency of interest as follows¹⁴:

$$L_{a2nd} = L_{pinc} + 10 \log \left[\left(\frac{\sigma_{rad}}{8.4t^2(\sigma_{rad} + 3.0\eta t)} \right) \right] \quad (10)$$

In this formula, L_{a2nd} is the secondary structure-borne-induced vibration level, L_{pinc} is the incident sound pressure level near the center of the structure of interest in the machinery room, t is the thickness of the structure plate, (inch), η is the structure's loss factor, and σ_{rad} is the structure's radiation efficiency.

Acknowledgments The authors' wish to acknowledge the contributions of many colleagues to the database that underlies the information presented in this chapter. In particular, the selection and summarizing of this material has benefited from discussions with Dr. Donald Ross, author of the text *Mechanics of Underwater Noise*, and Daniel Nelson, of Bolt, Beranek and Newman, Inc., who originated a major part of the SNAME noise and vibration performance predictions for shipboard machinery systems.

*For rectangular opening, $a_g = (LW/\pi)^{0.5}$, where L and W are the length and width, respectively; or a_g = the gap dimension for a small circumferential opening.

[†] $\lambda = 11$ m at 31.5 Hz, 5.4 m at 63 Hz, 2.7 m at 125 Hz, 1.4 m at 250 Hz, 0.7 m at 500 Hz, 0.34 m at 1000 Hz, 0.17 m at 2000 Hz, 0.085 m at 4000 Hz, and 0.04 m at 8000 Hz.

**NOISE AND VIBRATION
CONTROL IN BUILDINGS**

CHAPTER 102

INTRODUCTION – PREDICTION AND CONTROL OF ACOUSTICAL ENVIRONMENTS IN BUILDING SPACES

Louis C. Sutherland
27803 Longhill Drive
Rancho Palos Verdes, California

1 INTRODUCTION

The prediction of the acoustical and vibration environments in buildings must take into account acoustic, vibration, and seismic sources and wind excitation. Descriptors are commonly used to assess the environment both inside and outside of buildings. Practical details are needed to make the engineering analyses of these noise and vibration environments.

In providing suitable acoustical environments in buildings, it is important to evaluate the sound fields inside the building spaces through prediction and measurement. The control of the sound fields is primarily achieved by the acoustical treatment of the room surfaces. The control of noise in commercial, industrial, and residential buildings from external noise sources such as traffic and internal sources such as heating, ventilation, and air-conditioning (HVAC) and plumbing systems is also a matter of concern. Such control measures include the reduction of noise transmission from these external sources through the building shell and the evaluation and control of noise at the source from internal equipment. The special low-frequency problems associated with noise and vibration from wind and seismic loads on buildings need also to be addressed in providing satisfactory noise environments inside these buildings.

2 SOUND FIELDS AND REVERBERATION IN BUILDING SPACES

Sound fields in building spaces are distinguished by their spatial and temporal variations. The spatial pattern of sound fields in a room varies with the ratio of characteristic room dimensions to sound wavelengths, with the distance from sound source to receiver, and with the room shape. When the ratio of characteristic room dimensions to sound wavelength is much less than 10, the sound field will tend to be characterized by deterministic (sinusoidal) spatial variation of sound pressure levels in discrete room modes. At higher frequencies (shorter wavelengths), the sound field is usually described in statistical terms and can contain many such room modes, each covering a narrow frequency range corresponding to the resonance bandwidth of the mode. Such a sound field is often described as diffuse and may have a fairly uniform spatial distribution of sound pressure

levels. However, this description may not apply for rooms that are long and narrow such as corridors or other similarly shaped rooms with one dominant dimension.

The sound field inside a room is a composite of the *direct sound* from interior sources or from sound transmitted into the room and the *reverberant field*. The latter is comprised of all the sound remaining in the room after the first reflections from room surfaces. This characterization is especially meaningful for rooms with an approximately diffuse sound field. The magnitude of the direct sound field relative to that of the reverberant field plays a vital role in assessing the suitability of the room for various applications, such as for speech or music presentations or for environmental noise control design in industrial spaces. For the former, emphasis is usually placed on maximizing the ratio of direct to reverberant sound while control of the reverberant sound may be more critical for industrial work spaces.

The temporal variation in speech sounds in a room depends on the room reverberation or *room echo*. Biblical admonitions in Exodus 26(7) to "... make curtains of goats hair to be covering upon the tabernacle" and the guidance by the Roman architect, Vitruvius to "... choose a site in which the voice may fall smoothly, and not be returned by reflection so as to convey an indistinct meaning"¹ are early examples of concern about acoustical treatment and reverberation in buildings well before room acoustics was understood. The first scientific study of room reverberation was carried out by Wallace Sabine in his pioneering study to correct the room acoustics of a lecture room at Harvard University.² By careful observations over 3 years of experiments on how the reverberation time in the room changed as the number of seat cushions were changed, Sabine was able to derive a basic relationship between the reverberation time, room volume, and the total acoustical absorption over the room surfaces. This relationship, known as the Sabine equation [Eq. (22) in Chapter 103] has been refined by alternate forms identified in Chapter 104 as the Norris–Eyring and the Millington–Sette equations for higher accuracy when the average sound absorption coefficient over the room surfaces is small (<0.4). When the acoustical absorption treatment is very nonuniform over the room surfaces, or the room is very long or narrow (e.g., a non-Sabine room),² a further refinement is provided by

the Fitzroy or Fitzroy–Kuttruff equations described in Chapter 104. Nevertheless, the simple Sabine equation is often still used for approximate room acoustics evaluations. All of these expressions provide a measure of the room reverberation in terms of its reverberation time, RT_{60} , the time required for a sound that is suddenly turned off to decay by 60 dB.

One topic addressed briefly in this chapter is the spatial decay in the sound field in small office or conference rooms or in industrial spaces—all of which contain a large number of furnishings or machinery. Sound scattering by these objects causes the sound field from a single source to decay with distance in a manner not predicted by diffuse field theory [Eq. (6) in Chapter 104]. This anomalous decay with distance of the total sound field was found, empirically, by Schultz to have a decay rate of -3 dB/double distance (DD) for a wide range of small furnished spaces.³ In contrast, diffuse field theory dictates that the decay should be -6 dB/DD close to the source and then reach a constant value in the reverberant field of the source. Similarly, Hodgson has found the decay in the total sound field in industrial halls to fall well below this asymptotically zero rate of decay far from a source as dictated by diffuse field theory (see Ref. 7 in Chapter 104).

Chapter 104 also briefly treats sound absorption in the air, which is important in large rooms at high frequencies, especially at high temperatures and low relative humidity. The end of the chapter reviews the important aspects of the design of various forms of porous acoustical absorbing materials best suited for high frequencies and flexible panel absorbers better suited for low frequencies.

3 NOISE RATINGS AND DESCRIPTORS FOR BUILDING AND OUTDOOR ACOUSTICAL ENVIRONMENTS

The various ratings and descriptors considered in Chapters 105 to 115 are used for a wide range of acoustical environment problems. These include establishing noise control design goals for internal building structure or equipment components, the exterior structural shell, or for land-use planning guidelines. They also include assessment of environmental impact or acceptability of both outdoor and indoor noise environments or assessment of the suitability of indoor acoustical environments for speech communication. More specifically, these chapters treat ratings and descriptors for:

- Acoustical performance of building components for laboratory or field measurements (Chapters 105 and 106)
- Acceptable noise environments in offices for activity involving speech privacy and speech communication requirements (Chapters 109 and 110)
- Building assemblies for building codes to achieve required sound isolation (Chapter 110)
- Rating or noise control design of building equipment and services such as HVAC (Chapters 111 and 113)

- Acceptable noise environments inside residences to avoid annoyance (Chapter 114)
- Acceptable noise environments inside industrial or commercial buildings to avoid annoyance (Chapter 115)
- Outdoor environments from any outdoor noise source or from specific noise sources such as highway traffic relative to annoyance criteria (Chapters 114 and 115)

The wide application of these descriptors makes in unavoidable that they be also applied in many other chapters in this handbook. For example, noise descriptors needed to assess industrial plant noise environments for hearing conservation concerns (see Chapter 36), apply some elements of descriptors utilized for evaluation of industrial or commercial noise environments.

All of the descriptors share one element in common—they incorporate some measure of the frequency content of the acoustical environment being evaluated. This may be through use of a frequency weighting, such as an A-weighting for measurement of an A-weighted sound pressure level by a sound level meter that incorporates an A-weighting frequency response in its measurement system. Alternatively, frequency content of a sound may be assessed by matching its octave band spectrum to a fixed set of octave band spectrum shape contours to define its noise rating—for example, a noise criterion (NC) value. A similar spectrum contour matching process is employed to establish a sound transmission class (STC) or impact isolation class (IIC) of the airborne or structure-borne sound transmission loss of a structural assembly measured by one-third octave band values of sound transmission loss.

One important refinement for such frequency-dependent descriptors is in the evaluation of speech privacy—an important measure of the suitability of an office space for productive work. In this case, the speech privacy index (SPI) is the sum of the frequency-dependent (A-weighted) noise reduction (NR) and the noise criterion (NC) rating. These and other forms of frequency-dependent descriptors are discussed in Chapter 109.

For time-varying (usually outdoor) noise environments, an energy average of the noise level is normally employed to provide a single number value, such as an A-weighted day–night average sound pressure level (DNL). This process provides a practical means of assessing acceptability of fluctuating noise environments over a fixed time period.

4 SOUND TRANSMISSION IN BUILDINGS

Sound transmission within a building occurs by transmission through the air in the spaces bounded by walls or roof/ceiling assemblies or by structural transmission through these assemblies. Chapter 105 provides an overview of theory and measurements of sound transmission in buildings based on the chapter author's years of experience with NRC in Canada in laboratory measurements of airborne and structure-borne sound transmission through building wall and

floor/ceiling assemblies. Chapter 105 is supported with a list of 69 references emphasizing measured data. (A periodically updated source for such sound transmission data is also provided by Ref. 4 in Chapter 105). Key elements treated in this chapter are briefly reviewed here.

4.1 Airborne Sound Transmission

For the simplest case of a solid single-leaf wall with very low stiffness, the transmission of airborne sound through the wall roughly follows the so-called mass law. That is, the sound transmission loss increases in direct proportion to the surface mass of the wall and the frequency of the incident sound. Theoretically, doubling the surface mass or the frequency increases the wall sound transmission loss (STL) by 6 dB. While this simple mass law does, in fact, describe a general trend in STL for many constructions, there are many important deviations from this simple model. These include the dip in the mass law transmission loss at the so-called coincidence frequency of the wall, typically in the range of 2000 to 5000 Hz, where the trace wavelength of the incidence sound wave matches the structural bending wavelength of the wall. Other important deviations from the mass law occur, for double-leaf walls, at the mass–airspace–mass resonance frequency (generally below 200 Hz) of the double-leaf system and the simple acoustical resonance frequencies (typically in the range of 2000 to 3000 Hz) for the air gap between the wall leaves. The sound transmission loss of a composite wall must also consider the sound transmission loss of each of the fenestrations, such as windows and doors, combined with that of the basic wall.

4.2 Structural or Impact Sound Transmission

Transmission of impact sound through a floor–ceiling assembly, quantified by a single number impact insulation class (IIC), is obtained from measurements using a standard impact source (tapping machine). It is strongly dependent on structural details of the assembly, including any floor covering. In this respect, a misleadingly high IIC rating can be obtained when carpeting is employed on the same floor driven by the tapping machine. While beneficial for reducing impact noise, such as heel clicks, the actual impact noise reduction may not be as high as indicated by the IIC rating. Measured IIC ratings are provided by many of the references in Chapter 105 and in Ref. 4 of this chapter.

An important factor to be considered in evaluating transmission of airborne and structure-borne sound through a structure is the occurrence of flanking transmission paths. These can short-circuit the intended transmission path to reduce its effectiveness.

5 PREDICTION AND CONTROL OF NOISE AND VIBRATION FROM BUILDING EQUIPMENT

The application of the various descriptors considered in Section 3 is especially important in evaluation of interior sources of noise and vibration in buildings and determination of methods for their control.

5.1 Heating, Ventilation, and Air-Conditioning Systems

A dominant interior noise source in most buildings is the heating, ventilation, and air-conditioning equipment. Methods for noise assessment and control are reviewed in Chapters 110 and 111, in the references cited therein, and in many similar sources.^{5–7} HVAC noise control cannot always invoke the classical *source–path–receiver* noise control model. In this case, the source cannot always be isolated to just one location. HVAC noise can arise from several sources: the circulation fan and its motor, the air-conditioning compressor and its motor, the aeroacoustic noise generated by turbulence in the ventilation duct system, and by turbulence-generated noise at the duct diffuser or outlet. Each of these sources are amenable to noise control measures by several methods. These include selection of low-noise fan designs, that is, fans that minimize the rate of change of momentum of the air through the fan blades, minimization of turbulence in the ducts by use of aerodynamically smooth turning vanes at duct elbows or by reducing discharge airflow rates at the outlet diffuser. An important factor in such aeroacoustic noise control measures is that for such sources, sound intensities can vary as the (turbulent) air velocity to the fourth to eighth power, depending on the aero-acoustic source mechanism. Thus, reduction of airflow velocities and minimization of turbulence in any part of the system is highly desirable.

For HVAC systems, the path most readily subject to noise control is the duct system where duct lining and duct geometry at junctions, corners, or at mixing boxes play a vital role. Vibration isolation of the moving components as well as the duct supports is also essential for good control of structurally transmitted HVAC system noise. At the diffuser or outlet, the path is really the receiving room, and appropriate sound absorption at the surfaces of the room, as discussed in Chapter 104, provide control of the reverberant sound from the HVAC diffusers.

5.2 Noise Control of Other Interior Sources of Noise in Buildings

In addition to HVAC systems, other sources of building equipment noise can include steam turbines, transformers, elevators, and plumbing systems. Prediction and noise and vibration control methods for such building services equipment are treated in Chapter 113. For open plan offices, sound masking systems to help maintain a high speech privacy index are another source of interior noise in office buildings. The design and evaluation of such systems are treated in Chapter 109.

6 PREDICTION AND CONTROL OF NOISE IN SINGLE- AND MULTIFAMILY HOUSING AND IN COMMERCIAL AND PUBLIC BUILDINGS

The control of ambient noise inside single-family dwellings, other than from occupants, is treated in Chapter 114 primarily in terms of noise intrusion from outdoor sources such as highway traffic or aircraft.

Thus, the focus is on noise isolation provided by the exterior building shell. This necessarily also draws on the noise control and noise rating concepts considered earlier in this part.

For multifamily housing, in addition to noise control for these external sources, primary emphasis is normally placed on noise isolation between dwelling units—either units on the same floor separated by a part wall or one above the other separated by a floor-ceiling system. In this case, the noise source may be loud conversation or TV in one room adjacent to a bedroom of another dwelling, heel impacts on the floor above this bedroom, or annoying plumbing noise heard in an adjacent apartment. Litigation by angry apartment dwellers against the builder or developer of multifamily dwellings that have failed to incorporate adequate airborne or structure-borne noise isolation between dwellings is all too common. One of the causes of such problems is the systematic failure of developers, building designers, and building construction trades to recognize or appreciate the many airborne and structure-borne paths that building sounds can take between different parts of an apartment building. Remedial action to correct such shortcomings is invariably very expensive for all concerned—far more expensive than the initial cost of proper noise and vibration control design that is correctly executed. Laboratory test data and advanced analytical design methods, including statistical energy analysis (SEA) and finite element models (FEM) are available to support the design effort called for by the noise and vibration control problems addressed in this section.

The control of ambient noise inside commercial and industrial buildings is covered in Chapter 115 in terms of noise intrusion from outdoor sources such as traffic or aircraft, as in Chapter 114, and requirements for both noise isolation for exterior and interior walls and reverberation times for interior spaces for various uses. The focus is on specific design specifications covering these problems. Again, this draws on the noise control and noise rating concepts considered earlier.

7 ATYPICAL NOISE AND VIBRATION IN BUILDINGS

A few special problems in building noise and vibration are treated in the last three chapters in this part X.

7.1 Noise and Vibration Induced by Wind

As high-rise buildings with curtain walls and/or aerodynamically shaped surfaces become more common, wind-induced vibration of such buildings has become more significant. Dynamic (time-varying) wind loads on buildings, treated in Chapter 116, usually depend on the magnitude and fluctuating nature of the wind, its vertical profile (dependent on ground roughness, i.e., buildings, trees, etc.), and the type and shape of the structure being driven by the wind. The latter factors govern the aerodynamic forces attributable to the wind. Also involved may be the frequency of fluctuating forces induced by structural response to the wind and by vortex shedding or buffeting in the wake of the wind

incident on the structure. One classic example of such wind-induced dynamic loads is the catastrophic collapse of the 470-m-long Tacoma Narrows (suspension) Bridge near Tacoma, Washington, in November 1940. Sustained winds of only 16 to 19 m/s induced swaying vibration and finally catastrophic torsional oscillation of the deck at a frequency of 0.2 Hz.⁸ The failure was finally attributed to aerodynamic instability as a self-excited vibration of the thin bridge deck. This deck acted much like an aircraft wing to generate sufficient lift and cause unstable torsional vibration, eventually resulting in the structural failure of the suspension system and the deck. Lessons learned from this unforeseen incident now include a requirement that such similar suspension bridges undergo model tests in a wind tunnel prior to construction. Similar tests or analyses are now common in the design of high-rise buildings.

More routine structural vibration responses to wind are considered in this chapter. These include the frequency spectrum of vortex shedding or wake buffeting forces on a structure and the gusts or random fluctuations in the velocity of wind incident on a building. For example, the peak frequency of the broad spectrum associated with vortex shedding from a cylinder-like structure is the Strouhal frequency approximately equal to about 0.1 to 0.2 times the ratio of wind speed to a characteristic dimension normal to the wind vector. When this peak in the vortex frequency spectrum is close to a resonance frequency of a structure, resonant wind-induced structural vibration may occur. Fluctuations in speed of horizontal wind also have a broad frequency spectrum extending up to about 0.2 Hz but with a peak at about 0.015 Hz,⁹ well below resonance frequencies of buildings. However, annoying or uncomfortable wind-induced vibration of elastic building structures can occur from steady or fluctuating aerodynamic forces from the wind.¹⁰ Such phenomena and other aspects of wind-induced building vibration are reviewed in Chapter 116.

7.2 Seismic-Induced Building Vibration

Continuing the concerns about vibration response of structures to dynamic loads, Chapter 117 considers seismic response and design of buildings to earthquakes. Related building design considerations include the frequency response of building vibration modes, their time-history response to dynamic loads, damping methods to minimize resonance response and dynamic loads, or responses of secondary building services such as plumbing and electrical services. Analytical modeling for such building responses can range from simple shock spectra analyses providing estimates of responses for mass-spring-damper models of building modes to complex finite element dynamic models capable of evaluating building vibration in great detail. A thorough overview of these approaches is provided in Chapter 117 with support by extensive references.

A critical element in the design of building for earthquakes is the establishment of a “design earthquake” spectra of ground acceleration, velocity, or displacement. These are frequently established on the basis of measured ground motion of actual earthquakes

in one location giving consideration to possible differences in soil conditions between the design and the measured sites. Support in evaluating the dynamic stress response of a structure to an earthquake could be provided by the classic relationship by Hunt.¹¹ This states that the maximum stress in a structure vibrating in one of its normal modes is proportional to what might be called its *structural Mach number*, the ratio of the maximum structural modal velocity to the longitudinal speed of sound in the structure.¹² The proportionality constant is the modulus of elasticity of the structure multiplied by a shape- and material-dependent factor varying from about 0.9 to 2. This relationship between structural stress and velocity helps explain the common use of a maximum structural velocity of the order of 0.05 m/s (2 in./s) as a damage threshold for structures exposed to surface mining blasts.¹³

7.3 Low-Frequency Noise in Buildings

The frequent use of low-cost, light-weight timber construction for multifamily structures and the proliferation of loud home hi-fi systems and other interior noise sources has aggravated problems in low-frequency noise environments in buildings. Test data and design methods to achieve high sound isolation in the frequency range from 400 down to 50 Hz or lower are often inadequate to eliminate the presence of annoying low-frequency noise indoors. The last chapter in Part X, Chapter 118, covers this problem, focusing on anomalies in low-frequency sound isolation measurements, the large spatial variation in sound pressure levels for discrete low-frequency room modes. It identifies practical design concepts and remedial correction measures that can be employed to minimize the problem.

CHAPTER 103

ROOM ACOUSTICS

Colin H. Hansen
School of Mechanical Engineering
University of Adelaide
Adelaide, South Australia, Australia

1 INTRODUCTION

The acoustics of rooms can be divided into low- and high-frequency regions. Sound in rooms is strongly affected by the reflective properties of the room surfaces. When the room surfaces are highly reflective, multiple reflections occur, and in the high-frequency range, a reverberant field will be established in addition to the direct field from the source. Thus, at any point in such a room, the overall sound pressure level is a function of the energy contained in the direct and reverberant fields.

At low frequencies, where the ratio of the wavelength to room dimension is greater than about 0.1 and where there are relatively few acoustic modes resonant in an octave band, the sound field may be described in terms of a superposition of sound fields corresponding to each normal mode in the frequency range of interest as well as modes immediately outside the frequency range of interest. However, the number of acoustical resonances in a room increases very rapidly as the frequency of excitation increases. Consequently, in the high-frequency range, the possible resonances become so numerous that they cannot be distinguished from one another. Thus, in terms of total energy density (but not sound pressure), the sound field in the regions away from the source (reverberant field) becomes relatively uniform. In this frequency range, the resulting sound field is essentially diffuse and may be described in statistical terms or in terms of average properties.

A room used for assembly and general living and in which one dimension does not exceed any other by more than a factor of 3 is generally referred to as a Sabine enclosure, named after the man who initiated investigation of the acoustical properties of such rooms. Rooms in which one dimension is much

smaller than the other two are called flat rooms and are characteristic of many industrial facilities.

2 WAVE ACOUSTICS AND NORMAL MODES

The following sections on room acoustics are by necessity brief. For more detailed discussions, including practical applications, textbooks on the subject should be consulted.¹⁻⁴

In the low-frequency range, the sound field in an enclosure is dominated by standing waves at certain characteristic frequencies. Large spatial variations in the reverberant sound field are observed if the enclosure is excited with pure-tone sound, and the sound field in the enclosure is said to be dominated by resonant or modal response. This is illustrated in the low-frequency range of Fig. 1, which shows the sound pressure level measured at a microphone in the corner of the room as the room was excited by a loudspeaker in another corner. The electrical signal into the speaker was sinusoidal and was kept at a constant amplitude while the frequency was slowly increased. In this example, the room was a rectangular reverberation chamber with concrete walls having very low values of absorption coefficient. The room volume was 180 m³ and the surface area was 200 m². The mode numbers identified on the figure refer to the number of nodes (planes of sound pressure minima or theoretically zero sound pressure) in the standing-wave pattern along each of the Cartesian axes. Thus "0,1,0" refers to one planar node in the *y* direction (in the center of the room) and no nodes in the other two directions. Some mode shapes for a rectangular room are illustrated in Fig. 2.

When a source of sound in an enclosure is turned on, the resulting sound waves spread out in

Figure 1 Measured sound pressure level frequency response of a 180-m³ rectangular room. Below 80 Hz, room resonances are identified by mode numbers. Above about 80 Hz, peaks in the room response cannot be associated with room resonances identified by mode numbers.

Figure 2 Some low-order mode shapes of a rectangular room. The plus and minus signs represent the phase of the sound pressures. Plus is 180° out of phase with minus.

all directions from the source. When the advancing sound waves reach the walls of the enclosure, they are reflected, generally with a small loss of energy, eventually resulting in waves traveling around the enclosure in all directions. If each path that a wave takes is traced around the enclosure, there will be certain paths of travel that repeat upon themselves to form normal modes of vibration, and at certain frequencies, waves traveling around such paths will arrive back at any point along the path in phase. Amplification of the wave disturbance will result and the normal mode will be resonant. When the frequency of the source equals one of the resonance frequencies of a normal mode, resonance occurs and the interior space of the enclosure responds strongly, being only limited by the absorption present in the enclosure. As waves traveling along the same path but in opposite directions produce standing waves, a normal mode may be characterized as a system of standing waves, which in turn is characterized by nodes and antinodes. Where the oppositely traveling waves arrive in pressure antiphase, pressure cancellation will occur, resulting in a pressure minimum called a node. Similarly, where the oppositely traveling waves arrive in pressure phase, pressure amplification will occur, resulting in a pressure maximum called an antinode.

In an enclosure at low frequencies, the number of resonance frequencies within a specified frequency range will be small. Thus, at low frequencies, the response of a room as a function of frequency and location will be quite irregular; that is, the spatial distribution in the reverberant field will be characterized by pressure nodes and antinodes.

A rectangular room provides a convenient model for understanding modal response and the placement of sound absorbents for sound control. However, it should be emphasized that modal response is by no means peculiar to rectangular or even regular-shaped rooms. Modal response characterizes enclosures of all shapes. Splayed, irregular, or odd numbers of walls will not prevent resonances and accompanying pressure nodes and antinodes in an enclosure constructed of reasonably reflective walls; nor will such peculiar construction necessarily result in a more uniform distribution in frequency of the resonances of an enclosure than may a rectangular room of appropriate dimensions. However, it is simpler to calculate the resonance frequencies and mode shapes for rectangular rooms.

For sound in a rectangular enclosure, the resonance frequency of the n th mode is given by¹

$$f_n = \frac{c}{2} \sqrt{\left(\frac{n_x}{L_x}\right)^2 + \left(\frac{n_y}{L_y}\right)^2 + \left(\frac{n_z}{L_z}\right)^2} \quad (\text{Hz}) \quad (1)$$

In this equation the subscript n on the frequency variable f indicates that the particular solutions or “eigen”-frequencies of the equations describing the sound field in the room are functions of the particular mode numbers n_x , n_y , and n_z , and c is the speed of sound in the room space. The sound pressure distribution for the n th mode can be shown to be

$$p_n = \bar{p}_n \cos\left(\frac{\pi n_x x}{L_x}\right) \cos\left(\frac{\pi n_y y}{L_y}\right) \cos\left(\frac{\pi n_z z}{L_z}\right) e^{j\omega t} \quad (2)$$

The mode numbers n_x , n_y , and n_z take on all positive integer values including zero, and the bar over the p represents a modal amplitude (time and space invariant). There are three types of normal modes of vibration in a rectangular room, which have their analogs in enclosures of other shapes. They may readily be understood as follows:

1. Axial modes for which only one mode number is not zero, which correspond to wave travel back and forth parallel to an axis of the room
2. Tangential modes for which one mode number is zero, which correspond to waves traveling essentially parallel to two opposite walls of an enclosure while successively reflecting from the other four walls
3. Oblique modes for which no mode number is zero, which correspond to wave travel oblique to all room surfaces

3 GEOMETRIC ACOUSTICS AND SOUND FIELD MODELING

In the field of architectural acoustics, there are a number of commercially available software packages that are used for modeling the enclosed sound field for the purpose of predicting sound pressure level distributions and reverberation time. These packages are primarily based on ray tracing and geometric acoustics. As a convenience in the modeling process, specular reflection of sound from a surface is modeled by assuming an additional sound source being located as far behind the surface as the original source is in front, as illustrated in Fig. 3. When the reflecting surface absorbs some of the incident energy, the image source is made weaker by the appropriate amount. The ratio of absorbed energy to incident energy is referred to as the absorption coefficient of the surface and is related to the surface construction and covering material. In many instances in auditoria, sound is not reflected from the room surfaces specularly. It is scattered and the reflection is considered diffuse. In this case, the modeling software assumes a new source to be located on the reflecting surface and radiating energy in all directions

Figure 3 Geometry illustrating reflection from a plane rigid surface.

so that the total radiated energy is the incident energy multiplied by $(1 - \alpha)$, where α is the surface absorption coefficient. Computer modeling is discussed in more detail in manuals available from software vendors and textbooks.⁵

4 BOUND BETWEEN LOW-FREQUENCY AND HIGH-FREQUENCY BEHAVIOR

There is a need for a quantitative definition for the crossover from the low-frequency range, where modal analysis is appropriate, to the high-frequency range, where statistical analysis is appropriate. Reference to Fig. 1 provides no clear indication of a possible bound from clearly distinguishable resonance peaks to where the individual resonance peaks cannot be separated. Rather, a continuum of gradual change is observed. However, it is possible to determine a bound analytically, but to understand the determination of the bound, called here the crossover frequency, three separate concepts are required: modal density, modal damping, and modal overlap.

4.1 Modal Density

The number of modes, N , which may be excited in the frequency range from zero up to f is given by the following expression⁵:

$$N = \frac{4\pi f^3 V}{3c^3} + \frac{\pi f^2 S}{4c^2} + \frac{fL}{8c} \quad (3)$$

In Eq. (3), c is the speed of sound, V is the room volume, S is the room total surface area, and L is the total perimeter of the room. In a rectangular room the latter quantity is the sum of lengths of all edges. It has been shown that Eq. (3) has wider application than for rectangular rooms; to a good approximation it describes the number of modes in rooms of any shape.

For the purpose of estimating the number of modes that, on average, may be excited in a narrow frequency band, the derivative of Eq. (3), called the modal density, is useful. The expression for the modal density

is as follows:

$$\frac{dN}{df} = \frac{4\pi f^2 V}{c^3} + \frac{\pi f S}{2c^2} + \frac{L}{8c} \quad (4)$$

Equation (4) shows that the modal density increases with the square of the frequency, so that at high frequencies many modes will be excited by a narrow frequency band of noise. It is evident that at high frequencies the number of oblique modes [term 1 in Eq. (4)] will far exceed the number of tangential and axial modes, and to a good approximation at high frequencies the latter two mode types may be ignored.

4.2 Modal Damping and Bandwidth

Referring to Fig. 1, a bandwidth, Δf , may be defined and associated with each mode, being the frequency range about resonance over which the sound pressure level is within 3 dB of the peak value at resonance. The lower and upper frequencies bounding a resonance and defined in this way are known as the half-power points and are easily isolated for the first few modes (see Fig. 1).

The bandwidth, Δf , is dependent upon the damping of the mode; the greater the modal damping, the larger will be the bandwidth. If the modes are not well separated, the bandwidth can be estimated from the modal damping, which in turn can be estimated from the room reverberation time, T_{60} , using¹:

$$\Delta f = 2.20/T_{60} \quad (5)$$

where T_{60} is the time it takes for sound in the room to decay by 60 dB following cessation of the source of sound.

4.3 Modal Overlap

Modal overlap, M , is calculated as the product of the average bandwidth given by Eq. (5), and the modal density given by Eq. (4). Thus,

$$M = \Delta f dN/df \quad (6)$$

The modal overlap is a measure of the extent to which the resonances of a reverberant field cover the range of all possible frequencies within a specified frequency range. The concept is illustrated for a hypothetical case of a low modal overlap of 0.6 in Fig. 4. In the figure, three resonant modes, their respective bandwidths, and the frequency range of the specified frequency band are indicated.

In Fig. 4, the measurement band is 100 Hz wide and the bandwidth of each mode (3 dB down from the peak response) is 20 Hz.

4.4 Crossover Frequency

There are two criteria commonly used for determining the crossover frequency. The criterion that is chosen will depend upon whether room excitation with bands of noise or with pure tones is of interest.

If room excitation with one-third octave, or wider bands of noise, is to be considered, then the criterion

Figure 4 Sound pressure level response of three modes in a specified frequency range with a modal overlap of 0.6.

for statistical (high-frequency) analysis is that there should be a minimum of between three and six modes resonant in the frequency band. The exact number required is dependent upon the modal damping and the desired accuracy of the results. More modes are necessary for low values of modal damping or if high accuracy is required. If room excitation with a pure tone or a very narrow band of noise is of concern, then the criterion for reliable statistical analysis is that the modal overlap should be greater than or equal to 3.⁶

5 HIGH FREQUENCIES, STATISTICAL ANALYSIS

At high frequencies the sound field in a reverberant space may be thought of as composed of plane waves traveling in all directions with equal probability. If the mean square pressure amplitude of any traveling plane wave is on average the same, independent of direction, then the sound field is said to be diffuse. In a reverberant space, the sound field is diffuse when the modal overlap is 3 or greater, in which case the sound field steady-state frequency response is essentially a random phenomenon.

In a diffuse (reverberant) field, sound propagation in all directions is equally likely, and consequently the sound intensity at any point in the field is zero. However, an effective intensity associated with power transmission in a specified direction can be defined, and this is the intensity incident on the walls of the room. According to Bies and Hansen,¹ this effective sound intensity I in any direction may be written in terms of the time-averaged energy density, ψ , as

$$I = \psi c / 4 \quad (7)$$

Bies and Hansen¹ derive the following expression for the time-averaged energy density in terms of the space-averaged mean square pressure, $\langle p^2 \rangle$, which holds for

one-, two-, and three-dimensional sound fields:

$$\psi = \langle p^2 \rangle / (\rho c^2) \quad (8)$$

where ρ is the density of the medium containing the sound field.

Substitution of Eq. (8) into Eq. (7) gives the following expression for the effective intensity in one direction a diffuse field:

$$I = \langle p^2 \rangle / (4 \rho c) \quad (9)$$

5.1 Steady-State Response

At any point in a room, the sound field is a combination of the direct field radiated by the source and the reverberant field.

The sound pressure squared due to the direct field at a point in the room at a distance r and in a direction (θ, ϕ) , in the far field of a source, may be written as¹

$$\langle p^2 \rangle_D = W \rho c D_\theta / 4 \pi r^2 \quad (10)$$

The quantity D_θ is the directivity factor of the source in direction (θ, ϕ) , and W is the sound power radiated by the source in watts.

Consider that the direct field must be once reflected to enter the reverberant field. The fraction of energy incident at the walls, which is reflected into the reverberant field is $(1 - \bar{\alpha})$, where $\bar{\alpha}$ is the average surface absorption coefficient, representing the fraction of incident energy absorbed by the room boundaries. Using Eq. (9), and noting that the sound power incident on a surface is the area of the surface multiplied by the sound intensity, the sound pressure squared due to the reverberant field may be written as

$$\langle p^2 \rangle_R = 4 W \rho c (1 - \bar{\alpha}) / (S \bar{\alpha}) \quad (11)$$

The sound pressure level at any point due to the combined effect of the direct and reverberant sound fields is obtained by adding together Eqs. (10) and (11) and taking 10 log of both sides (as described in more detail in Chapter 2 and in Bies and Hansen¹). Thus,

$$L_p = L_w + 10 \log_{10} \left(\frac{D_\theta}{4 \pi r^2} + \frac{4}{R} \right) + 10 \log_{10} \left(\frac{\rho c}{400} \right) \quad (12)$$

At 20°C, where $\rho c = 414$ (in the International System of Units), there would be an error of approximately 0.1 dB if the last term in Eq. (12) is omitted. The sound pressure level, L_p , is referenced to 20 μ Pa and the sound power level, L_w , is referenced to 10^{-12} W. Equation (12) has been written in terms of the room constant R where the room constant is

$$R = \frac{S \bar{\alpha}}{1 - \bar{\alpha}} \quad (13)$$

In common industrial spaces, which have lateral dimensions much greater than their height, Eq. (12) underpredicts reverberant field noise levels close to the

noise source and overpredicts levels far away from the source.⁷

In cases where there are many sources, Eq. (12) may be written as

$$L_p = L_w + 10 \log_{10} \left(\sum_1^n \frac{d_i D_i}{4\pi r_i^2} + \frac{4}{R} \right) \quad (14)$$

In the above equation the weighting factor d_i and the directivity factor D_i for the i th source have been introduced. The weighting factor is calculated as $d_i = W_i/W$ where W_i is the sound power of the i th source and W is the arithmetic sum of all sources, both in consistent units. The directivity factor D_i may be taken as 1 for a source raised up off the floor and 2 for a source on the floor. Alternatively, if the directional properties of the source are known, then this information may be used instead. The quantities r_i are the linear distances from the assumed acoustical centers of the several sources to the point of observation.

5.2 Transient Response

If sound is introduced into a room, the reverberant field level will increase until the rate of sound energy introduction is just equal to the rate of sound energy absorption. If the sound source is abruptly shut off, the reverberant field will decay at a rate determined by the rate of sound energy absorption. The time required for the reverberant field to decay by 60 dB, called the reverberation time, is the single most important parameter characterizing a room for its acoustical properties. For example, a long reverberation time may make the understanding of speech difficult but may be desirable for organ recitals.

As the reverberation time is directly related to the energy dissipation in a room, its measurement provides a means for the determination of the energy absorption properties of a room. Knowledge of the energy absorption properties of a room in turn allows estimation of the resulting steady-state sound pressure level in the reverberant field when sound of a given power level is introduced. The energy absorption properties

of materials placed in a reverberation chamber may be determined by measurement of the associated reverberation times of the chamber (see Chapter 104 for details of measurement procedures), with and without the material under test in the room. The Sabine absorption coefficient, which is assumed to be a property of the material under test, is determined in this way and standards⁸⁻¹⁰ are available that provide guidance for conducting these tests (see also Chapter 104). Some typical values of Sabine absorption coefficient are listed in Table 1.

At high frequencies, the reverberant field may be described in terms of a simple differential equation, which represents a gross simplification of the physical process but nonetheless gives generally useful results.

Using Eq. (7), the relation that the rate of energy absorbed by a surface is the incident intensity multiplied by the surface area and the surface absorption coefficient, and the observation that the rate of change of the energy stored in a reverberant field equals the rate of supply, W_0 , less the rate of energy absorbed, W_a , gives the following result:

$$W = Vd\psi/dt = W_0 - \psi Sc\bar{\alpha}/4 \quad (15)$$

Introducing the dummy variable:

$$X = (4W_0/Sc\bar{\alpha}) - \psi \quad (16)$$

and using Eq. (16) to rewrite Eq. (15), the following result is obtained:

$$\frac{1}{X} \frac{dX}{dt} = -\frac{Sc\bar{\alpha}}{4V} \quad (17)$$

Integration of the above equation gives

$$X = X_0 e^{-Sc\bar{\alpha}t/4V} \quad (18)$$

where X_0 is the initial value.

Two cases will be considered. Suppose that initially, at time zero, the sound field is nil and a source of power, W_0 , is suddenly turned on. The initial conditions are time $t = 0$ and sound pressure $\langle p^2 \rangle_0 = 0$. Use of Eq. (8) and substitution of Eq. (16) into Eq. (18) gives the following expression for the resulting reverberant field at any later time t :

$$\langle p^2 \rangle = \frac{4W_0\rho c}{S\bar{\alpha}} (1 - e^{-Sc\bar{\alpha}t/4V}) \quad (19)$$

Alternatively, consider that a steady-state sound field has been established when the source of sound is suddenly shut off. In this case, the initial conditions are time $t = 0$, sound power $W_0 = 0$, and sound pressure $\langle p^2 \rangle = \langle p_0^2 \rangle$. Again, use of Eq. (8) and substitution of Eq. (16) into Eq. (18) gives, for the decaying reverberant field at some later time t :

$$\langle p^2 \rangle = \langle p_0^2 \rangle e^{-Sc\bar{\alpha}t/4V} \quad (20)$$

Taking logarithms to the base 10 of both sides of Eq. (20) gives the following:

$$L_{p0} - L_p = 1.086Sc\bar{\alpha}t/V \quad (21)$$

Equation (21) shows that the sound pressure level decays linearly with time and at a rate proportional to the Sabine absorption $S\bar{\alpha}$. It provides the basis for the measurement and the definition of the Sabine absorption coefficient $\bar{\alpha}$.

Sabine introduced the reverberation time, T_{60} (seconds), as the time required for the sound energy density level to decay by 60 dB from its initial value. He showed that the reverberation time, T_{60} , was related to the room volume, V , the total wall area including floor and ceiling, S , the speed of sound, c , and an absorption coefficient, $\bar{\alpha}$, which was characteristic of the room and generally a property of the bounding surfaces. Sabine's reverberation time equation, which follows from Eqs. (20) and (21) with $L_{p0} - L_p = 60$, may be written as follows:

$$T_{60} = \frac{55.25V}{Sc\bar{\alpha}} \quad (22)$$

Measurement of the reverberation time is discussed in Chapters 43 and 104. There is also special-purpose equipment and special functions on some general-purpose instrumentation to allow semiautomatic measurements.

6 FLAT ROOMS

Many factories are large laterally compared to their height, and for these the reverberant field will steadily decay as the distance from the sound source increases. In Chapter 7 of Bies and Hansen,¹ flat rooms with a

Figure 5 Direct and reverberant sound fields in a flat room of height a with diffusely reflecting floor and ceiling as a function of the normalized distance from source to receiver. The reverberant field contribution is shown as a function of the energy reflection coefficient, β , assumed the same for floor and ceiling. The direct field is indicated by the dashed diagonal straight line.

range of different surface conditions as well as tunnels are discussed. Here, only flat rooms with diffusely reflecting surfaces are discussed as this is a good model for most factory situations where there is often pipework on the ceiling and machinery on the floor to scatter the incident sound. Determination of effective surface reflection coefficients generally requires an empirical approach. For noise control purposes, the proposed model is useful in spite of the difficulty in determining surface reflection coefficients, as it provides the basis for determining the effectiveness of the introduction of measures designed to reduce the floor and/or ceiling reflection coefficients. Based on the work of Kuttruff¹¹ and the analysis in Bies and Hansen,¹ the reverberant and direct sound fields in a flat room with a diffusely reflecting floor and ceiling may be represented as in Fig. 5, where the direct and reverberant fields are shown separately as a function of distance, r from the source for different values of surface reflection coefficient. The ordinate axis represents the sound pressure squared (either reverberant or direct), normalized with respect to the source sound power and the room height squared.

CHAPTER 104

SOUND ABSORPTION IN ROOMS

Colin H. Hansen
School of Mechanical Engineering
University of Adelaide
Adelaide, South Australia, Australia

1 INTRODUCTION

The sound absorption coefficient of a material is the fraction of the sound energy absorbed by the material compared with the sound energy incident. Sound in an enclosed space is strongly affected by the absorptive properties of the enclosing surfaces and any other objects in the room. Sound absorption in enclosures plays an important part in the determination of sound pressure levels resulting from the operation of interior and exterior sound sources of known sound power output, as well as in determining the amount of reverberation or “liveliness” of the enclosure, which is quantified in terms of its reverberation time. From knowledge of the sound absorption in an enclosure, obtained from estimations of the acoustical properties of the surfaces or from measurements of the reverberation time, one can calculate the effect of absorption on the sound pressure level, created by a sound source, in an enclosure. Relationships have been developed between sound absorption, acoustic impedance, and flow resistance for acoustically absorptive materials.

2 ENERGY ABSORPTION AT BOUNDARIES OF AN ENCLOSURE

The following sections on sound absorption in rooms are by necessity brief. For more detailed discussion, relevant books and standards should be consulted.¹⁻⁴

Consider a diffuse sound field in an enclosure and suppose that a fraction of the incident energy is absorbed upon reflection at the enclosure boundaries. Let the average fraction of incident energy absorbed be $\bar{\alpha}$, called the Sabine absorption coefficient. Implicit in the use to which the Sabine absorption will be put is the assumption that this absorption coefficient is strictly a property that may be associated with the absorptive material. Whatever the material, this assumption is not strictly true; it is a useful approximation that makes tractable an otherwise very difficult problem. The concept of absorption coefficient follows from the assumption that the walls of an enclosure may be considered to be locally reactive and thus characterized by an impedance, which is a unique property exhibited by the wall at its surface and is independent of interaction between the incident sound and the wall anywhere else. The assumption is then explicit that the wall response to the incident sound depends solely on local properties and is independent of the response at other points on the surface.

The locally reactive assumption has proven very useful for architectural purposes but is apparently of very little use in predicting interior noise in aircraft and vehicles of various types. In the latter cases, the modes

of the enclosed space couple with modes in the walls, and energy stored in vibrating walls contributes very significantly to the resulting sound field. In such cases, the locally reactive concept is not even approximately true, and neither is the concept of Sabine absorption that follows from it.

3 AIR ABSORPTION

In addition to energy absorption on reflection, some energy is absorbed during propagation between reflections. Generally, propagation loss due to air absorption is negligible, but at high frequencies above 500 Hz, especially in large enclosures, it makes a significant contribution to the overall loss.

Air absorption may be taken into account as follows. As shown by Bies and Hansen,¹ the mean distance, Λ , traveled by a plane wave in an arbitrarily shaped enclosure between reflections, is called the mean free path and is given by

$$\Lambda = \frac{4V}{S} \quad (1)$$

where V is the room volume and S is the room surface area. Note that several other longer and more complex derivations have been published many years earlier by various authors. It will now be assumed that the fraction of propagating sound energy lost due to air absorption between reflections is linearly related to the mean free path. If the fraction lost is not greater than 0.4, then the error introduced by this approximation is less than 10% (0.5 dB).

At this point many authors write $4m'V/S = \alpha_a$, for the contribution due to air absorption, and they provide tables of values of the constant m' as a function of temperature and relative humidity. However, it is possible to use values of air absorption, m , in terms of decibels per 1000 m as tabulated in the International Organization for Standardization (ISO) standard, ISO 9613/1-1993. In a distance of one mean free path the attenuation of sound is

$$\frac{4mV}{S} 10^{-3} = -10 \log_{10} e^{-4m'V/S} \quad (2)$$

Let

$$4m'V/S = \alpha_a \quad (3)$$

Thus,

$$\alpha_a = 4mV/(S10^4 \log_{10} e) = 9.21 \times 10^{-4} mV/S \quad (4)$$

Table 1 Attenuation due to Atmospheric Absorption

Relative Humidity (%)	Temperature (°C)	<i>m</i> (dB per 1000 m)						
		63 Hz	125 Hz	250 Hz	500 Hz	1 kHz	2 kHz	4 kHz
25	15	0.2	0.6	1.3	2.4	5.9	19.3	66.9
	20	0.2	0.6	1.5	2.6	5.4	15.5	53.7
	25	0.2	0.6	1.6	3.1	5.6	13.5	43.6
	30	0.1	0.5	1.7	3.7	6.5	13.0	37.0
50	15	0.1	0.4	1.2	2.4	4.3	10.3	33.2
	20	0.1	0.4	1.2	2.8	5.0	10.0	28.1
	25	0.1	0.3	1.2	3.2	6.2	10.8	25.6
	30	0.1	0.3	1.1	3.4	7.4	12.8	25.4
75	15	0.1	0.3	1.0	2.4	4.5	8.7	23.7
	20	0.1	0.3	0.9	2.7	5.5	9.6	22.0
	25	0.1	0.2	0.9	2.8	6.5	11.5	22.4
	30	0.1	0.2	0.8	2.7	7.4	14.2	24.0

Sources: Calculated from Sutherland⁵; see also the relevant ISO standard.⁶

Using the above relation, the total mean absorption coefficient, including air absorption may be written as

$$\bar{\alpha} = \bar{\alpha}_{\text{wcf}} + 9.21 \times 10^{-4} m V / S \quad (5)$$

where $\bar{\alpha}_{\text{wcf}}$ is the average surface absorption coefficient (walls, ceiling, and floor), representing the fraction of incident energy that is absorbed by the room boundaries. Some typical values of m are given in Table 1.

4 SOUND PRESSURE LEVEL IN AN ENCLOSURE

At any point in a room or enclosure, the sound field is a combination of the direct field radiated by the source and the reverberant field. Thus, the total sound energy measured at a point in a room is the sum of the sound energy due to the direct field and that due to the reverberant field (see Chapter 103) and is

$$L_p = L_w + 10 \log_{10} \left(\frac{D_\theta}{4\pi r^2} + \frac{4}{R} \right) + 10 \log_{10} \left(\frac{\rho c}{400} \right) \quad (6)$$

In common industrial spaces, which have lateral dimensions much greater than their height, Eq. (6) underpredicts reverberant field noise levels close to the noise source and overpredicts levels far away from the source.⁷ Equation (6) has been written in terms of the room constant R where the room constant is

$$R = \frac{S\bar{\alpha}}{1 - \alpha} \quad (7)$$

where values of Sabine absorption coefficients for areas S_i are known, perhaps by reference to a table of measured values. The mean Sabine absorption coefficient $\bar{\alpha}$ is calculated as the area-weighted average as follows:

$$\bar{\alpha} = \sum_i^n \frac{S_i}{S} \bar{\alpha}_i \quad (8)$$

The quantity $S_i \alpha_i$ has units of square feet or square metres, but in either case it has the name sabin. Here it will be called a metric sabin when it has the units of square metres. It is interesting to note that a seated audience in an auditorium has an absorption of about 0.45 metric sabins in the frequency range, 500 to 4000 Hz, 0.37 metric sabins at 250 Hz, and 0.23 metric sabins at 125 Hz.

The reduction in sound pressure level, L_p , in the reverberant field due to treatment with sound-absorbing material may be calculated using the following equation¹:

$$\Delta L_p = 10 \log_{10} |R_f / R_i| \quad (9)$$

Here R_i is the initial value and R_f is the final value of the room constant after the addition of absorbent.

5 EFFECT OF SOUND ABSORPTION ON REVERBERATION TIME

When sound is introduced into a room, the reverberant field level will increase until the sound energy introduction is just equal to the sound energy absorption. If the sound source is abruptly shut off, the reverberant field will decay at a rate determined by the rate of sound energy absorption. The time required for the reverberant field to decay by 60 dB is called the reverberation time and is the single most important parameter describing the acoustical properties of a room. The room absorption and reverberation time are related by the following equation, derived in Chapter 103:

$$T_{60} = \frac{55.3V}{Sc\bar{\alpha}} \quad (10)$$

The term, $S\bar{\alpha}$, is referred to as the equivalent absorption area, A , of a room and if the speed of sound, c , is set equal to 340 m/s², Eq. (30) of Chapter 4, which is the well-known Sabine equation, is obtained. It is interesting to note that the effective Sabine absorption coefficient used to calculate reverberation times in

spaces such as typical concert halls or factories is not the same as that measured in a reverberation room,^{8,9} which often leads to inaccuracies in predicted reverberation times. For this reason it is prudent to follow the advice given in the next section.

6 MEASUREMENT OF THE ROOM CONSTANT, R

Measurements of the room constant, R , given by Eq. (7), may be made using either a reference sound source or by measuring the reverberation time of the room in the frequency bands of interest.

6.1 Reference Sound Source Method

The reference sound source is placed at a number of positions chosen at random in the room to be investigated, and sound pressure levels are measured at a number of positions in the room for each source position. In each case, the measurement positions are chosen to be remote from the source, where the reverberant field of the room dominates the direct field of the source. The number of measurement positions for each source position and the total number of source positions used are usually dependent upon the irregularity of the measurements obtained. Generally, four or five source positions with four or five measurement positions for each source position are sufficient, giving a total number of measurements between 16 and 25. The room constant R for the room is then calculated using Eq. (6), excluding the direct field term, as measurements are made well away from the sound source, and rearranging the equation as follows:

$$R = 4 \times 10^{(L_w - L_p)/10} \quad (11)$$

In Eq. (11), L_p is the room average sound pressure level, measured away from the source and the enclosure walls. It is calculated using:

$$L_p = 10 \log_{10} \left[\frac{1}{N} \sum_{i=1}^N 10^{(L_{pi}/10)} \right] \quad (\text{dB re } 20 \mu\text{Pa}) \quad (12)$$

In Eq. (11) L_w is the sound power level (dB re 10^{-12} W) of the reference sound source, and in Eq. (12) N is the total number of measurements.

6.2 Reverberation Time Method

The second method is based upon a measurement of the room reverberation time. When measuring reverberation time in a room, the source of sound is usually a speaker driven by a random noise generator in series with a bandpass filter. When the sound is turned off, the room rate of decay is measured by using a sound level meter attached to a level recorder, which records the sound field in decibels as a function of time.

The reverberation time, T_{60} , in each frequency band is determined as the reciprocal sound pressure level decay rate obtained using the level recorder. The slope, generally measured as the best straight line fit to the recorded decay between 5 and 35 dB down from the

initial steady-state level, is used to determine the decay rate. Note that some instrumentation is capable of calculating reverberation times for all octave bands simultaneously without using a level recorder.

It is usual to employ several different microphone positions in the room, and to determine the reverberation times at each position. The value of T_{60} used in the subsequent calculations is then the average of all the values obtained for a given frequency band where Eq. (14) is used to obtain each average. Once found, the reverberation time, T_{60} , is used in Eq. (10), rearranged as follows, to calculate the room absorption. Thus,

$$S \bar{\alpha} = \frac{55.3V}{cT_{60}} \quad (\text{m}^2) \quad (13)$$

Note that when processing the data, average decay rates, not decay times, are needed! Thus, what is required is

$$\frac{1}{T_{60}} = \frac{1}{N} \sum_{i=1}^N \frac{1}{T_{60i}} \quad (14)$$

When observing reverberation decay curves (average sound pressure level versus time), it will be noted that for almost any room, two different slopes will be apparent. The steeper slope occurs for the initial 7 to 10 dB of decay, the exact number of decibels being dependent upon the physical characteristics of the room and contents. When this initial slope is extrapolated to a decay level of 60 dB, the corresponding time is referred to as the early decay time (EDT). The slope of the remainder of the decay curve, when extrapolated to 60 dB corresponds to what is commonly referred to as the reverberation time (RT). The ratio of EDT to RT as well as the absolute values of the two quantities are widely used in the design of architectural spaces. For more information see architectural acoustics books.^{3,10-13}

7 MEASUREMENT OF THE SABINE ABSORPTION COEFFICIENT, $\bar{\alpha}$

Sabine absorption coefficients for materials are generally measured in a laboratory using a reverberant test chamber. Procedures and test chamber specifications are described in various standards.¹⁴⁻¹⁶ The material to be tested is placed in a reverberant room and the reverberation time, T_{60} , is measured. The test material is removed and the reverberation time, T'_{60} , of the room containing no test material is measured next. Provided that the absorption of the reverberation room in the absence of the test material is dominated by the absorption of the walls, floor, and ceiling, the reverberation times are related to the test material absorption, $S\bar{\alpha}$, by the following equation [derived directly from Eq. (10)]:

$$S \bar{\alpha} = \frac{55.3V}{c} \left(\frac{1}{T_{60}} - \frac{S' - S}{S'T'_{60}} \right) \quad (\text{m}^2) \quad (15)$$

The quantity, S' , is the total area of all surfaces in the room, including the area of the material under test. Equation (15) is written with the implicit assumption that the surface area, S , of the test material is large

enough to measurably affect the reverberation time but not so large as to seriously affect the diffusivity of the sound field, which is basic to the measurement procedure. The standards recommend that S should be between 10 and 12 m² with a length-to-breadth ratio between 0.7 and 1.0.

In many cases, the absorption of a reverberation room is dominated by things other than the room walls, such as loudspeakers at low frequencies, stationary and rotating diffuser surfaces at low and midfrequencies, and air absorption at high frequencies. For this reason, the contribution of the room to the total absorption is often considered to be the same with and without the presence of the sample. In this case, the additional absorption due to the sample may be written as

$$S \bar{\alpha} = \frac{55.3V}{c} \left(\frac{1}{T_{60}} - \frac{1}{T'_{60}} \right) \quad (\text{m}^2) \quad (16)$$

Equation (16) is what appears in most current standards. Because the sample of absorbing material diffracts the sound field so that more energy falls on it than would fall on the same area of uncovered floor, it is possible to measure Sabine absorption coefficients that are in excess of 1.0, which does not make much sense as it implies that the material absorbs more sound than actually falls on it.

The measured value of the Sabine absorption coefficient is dependent upon the sample size, sample distribution, and the properties of the room in which it is measured. Because standards specify the room characteristics and sample size and distribution for measurement, similar results can be expected for the same material measured in different laboratories (although even under these conditions significant variations have been reported). However, these laboratory-measured values are used to calculate reverberation times and reverberant sound pressure levels in auditoria and factories that have quite different characteristics, which implies that under these circumstances, values of reverberation time, T_{60} , and reverberant field sound pressure level, L_p , calculated from measured Sabine absorption coefficients are approximate only. However, the errors in room constant calculations as a result of the errors in absorption coefficient measurements using Eq. (15) are much less than the errors that would be introduced using Eq. (11).

8 STATISTICAL ABSORPTION COEFFICIENT AND ITS DETERMINATION FROM MEASURED DATA

The statistical absorption coefficient differs from the Sabine coefficient in terms of how it is defined and measured. Whereas the Sabine absorption coefficient is measured in a reverberation room and defined in terms of a reverberation time, the statistical absorption coefficient is calculated for a material from measurements of the normal incidence absorption coefficient in an impedance tube. However, both coefficients are intended to describe the fraction of incident energy that the material absorbs in a randomly incident sound field each time there is a reflection.

Figure 1 Equipment for impedance tube measurement.

The normal incidence absorption coefficient may be measured using an impedance tube, which can be constructed from any heavy-walled tube, as shown in Fig. 1. The older and simpler method uses a movable microphone that traverses the length of the tube to map the sound field in the tube for a single-frequency sound. This method is slow but easily implemented. A much quicker method makes use of two fixed microphones and a digital frequency analysis system. However, both methods are described in standards and texts.^{1,17,18}

Implicit in the use of the impedance tube is the assumption that only plane waves propagate back and forth in the tube. This assumption puts upper and lower frequency bounds on the use of the impedance tube. Let d be the tube diameter if it is circular in cross section or the larger dimension if it is rectangular in cross section. Then the upper frequency limit (or cut-on frequency) is $0.586c/d$ for circular cross-section tubes and $0.5 c/d$ for rectangular tubes. Here, c is the speed of sound and the frequency limit is given in hertz. The low-frequency bound is given by the requirement that the length ℓ of the tube should be greater than $d + \frac{3}{4}c/f$ where f is the low-frequency bound in hertz.

When the material to be tested is in place and the resulting field within the impedance tube is explored, a series of maxima and minima will be observed. The maxima will be effectively constant in level, but the minima will increase in level as the distance from the surface of the test material is increased. For best results, it is recommended that successive minima be determined and extrapolated back to the surface of the sample by drawing a straight line joining the first two minima to the location corresponding to the surface of the sample on the plot of sound pressure level in decibels versus distance along the tube. The standing-wave ratio L_0 is then determined as the difference between the maximum level L_{\max} and the extrapolated minimum level L_{\min} .

The normal impedance Z_N of the test material, used in the calculation of the statistical absorption coefficient, can be calculated using:

$$\begin{aligned} K_0 &= 10^{L_0/20} \\ M &= 0.5(K_0 + K_0^{-1}) \\ N &= 0.5(K_0 - K_0^{-1}) \\ \theta &= 360(2D_1/\lambda - \frac{1}{2}) \quad (\text{degrees}) \quad (17) \\ R &= (M - N \cos \theta)^{-1} \\ X &= RN \sin \theta \\ Z_N/(\rho c) &= R + jX = \xi e^{j\beta} \end{aligned}$$

where

$$\beta = \tan^{-1}(X/R)$$

$$\xi = \sqrt{R^2 + X^2} \quad (18)$$

The statistical absorption coefficient can then be calculated using:¹⁹

$$\alpha_{st} = \left(\frac{8 \cos \beta}{\xi} \right) \left\{ 1 - \left(\frac{\cos \beta}{\xi} \right) \right.$$

$$\times \ln(1 + 2\xi \cos \beta + \xi^2) + \left[\frac{\cos(2\beta)}{\xi \sin \beta} \right]$$

$$\left. \times \tan^{-1} \left(\frac{\xi \sin \beta}{1 + \xi \cos \beta} \right) \right\} \quad (19)$$

9 STATISTICALLY BASED MODELS FOR REVERBERATION TIME CALCULATIONS

By treating the room response as a superposition of normal modes, Bies and Hansen¹ show how the following well-known reverberation time equation of Norris–Eyring may be derived:

$$T_{60} = -\frac{55.3V}{Sc \ln(1 - \bar{\alpha}_{st})} \quad (20)$$

This equation is often preferred to the Sabine equation by many who work in the field of architectural acoustics as some authors claim that it gives results that are closer to measured data.²⁰ However, Beranek and Hidaka²¹ obtained good agreement between measured and predicted reverberation times in concert halls using the Sabine relation. Of course, if sound absorption coefficients measured in a reverberation chamber are to be used to predict reverberation times, then the Sabine equation must be used, as the Norris–Eyring equation is only valid if statistical absorption coefficients are used.

Note that air absorption must be included in $\bar{\alpha}_{st}$ in a similar way as it is included in $\bar{\alpha}$ [Eq. (5)]. It is worth careful note that Eq. (20) is a predictive scheme based upon a number of assumptions that cannot be proven, and consequently inversion of the equation to determine the statistical absorption coefficient $\bar{\alpha}_{st}$ is not recommended.

With a further simplification, the famous equation of Sabine is obtained. When $\bar{\alpha}_{st} < 0.4$, an error of less than 0.5 dB is made by setting $\bar{\alpha}_{st} \approx \log_e(1 - \bar{\alpha}_{st})$ in Eq. (20), and then by replacing $\bar{\alpha}_{st}$ with $\bar{\alpha}$, Eq. (13) is obtained.

Alternatively, if in Eq. (20), the quantity, $\bar{\alpha}_{st}$ is replaced by $(1 - \beta_{st})$, where β_{st} is the mean statistical reflection coefficient, the following equation of Millington and Sette is obtained:

$$T_{60} = -\frac{55.3V}{Sc \ln \beta_{st}} \quad (21)$$

The quantity β_{st} is interpreted as the area-weighted geometric mean of the random incidence energy reflection coefficients, β_i , for all of the room surfaces; that is,

$$\bar{\beta}_{st} = \prod_{i=1}^n \beta_i^{S_i/S} \quad (22)$$

The quantity β_i is related to the statistical absorption coefficient α_i for surface i of area S_i by $\beta_i = 1 - \alpha_i$. It is of interest to note that although taken literally, Eq. (21) would suggest that an open window having no reflection would absorb all of the incident energy and there would be no reverberant field, the interpretation presented here suggests that an open window must be considered as only a part of the wall in which it is placed and the case of total absorption will never occur.

10 EMPIRICAL MODELS FOR REVERBERATION TIME CALCULATIONS

For calculating reverberation times in rooms for which the distribution of absorption was nonuniform (such as rooms with large amounts of absorption on the ceiling and floor and little on the walls), Fitzroy²² proposed the following empirical equation:

$$T_{60} = \frac{0.16V}{S} \left[\frac{-S_x}{\ln(1 - \bar{\alpha}_{x,st})} \right.$$

$$\left. + \frac{-S_y}{\ln(1 - \bar{\alpha}_{y,st})} + \frac{-S_z}{\ln(1 - \bar{\alpha}_{z,st})} \right] \quad (23)$$

where V is the room volume (m^3), S_x , S_y , and S_z are the total areas of two opposite parallel room surfaces (m^2), $\bar{\alpha}_{y,st}$, $\bar{\alpha}_{y,st}$, and $\bar{\alpha}_{z,st}$ are the average statistical absorption coefficients of a pair of opposite room surfaces [see Eq. (8)] and S is the total room surface area.

Neubauer²⁰ presented a modified Fitzroy equation, which he called the Fitzroy–Kuttruff equation, that gave more reliable results than the original Fitzroy equation. In fact, this equation has been shown to be even more accurate than the Norris–Eyring equation for architectural spaces with nonuniform sound absorption. The Fitzroy–Kuttruff equation is as follows:

$$T_{60} = \left(\frac{0.32V}{S^2} \right) \left[\frac{L_z(L_x + L_y)}{\bar{\alpha}_w} + \frac{L_x L_y}{\bar{\alpha}_{cf}} \right] \quad (24)$$

where L_x , L_y , and L_z are the room dimensions (m) and

$$\bar{\alpha}_{cf} = -\ln(1 - \bar{\alpha}_{st}) + \left[\frac{\beta_{cf}(\beta_{cf} - \bar{\beta}_{st})S_{cf}^2}{(\bar{\beta}_{st}S)^2} \right] \quad (25)$$

$$\bar{\alpha}_w = -\ln(1 - \bar{\alpha}_{st}) + \left[\frac{\beta_w(\beta_w - \bar{\beta}_{st})S_w^2}{(\bar{\beta}_{st}S)^2} \right] \quad (26)$$

where $\bar{\alpha}_{st}$ is the arithmetic mean over the six room surfaces of the surface-averaged statistical absorption coefficient, $\beta = (1 - \alpha)$ is the reflection coefficient, the subscript w refers to the walls and the subscript cf refers to the ceiling and floor. Other empirical schemes are discussed elsewhere.²³

Equations (10), (20), (21), (23), and (24) for reverberation time are all based on the assumption that the room dimensions satisfy the conditions for Sabine rooms (no one dimension greater than three times any of the other two) and that the absorption is reasonably well distributed over the room surfaces. However, in practice, this is not often the case and for rooms that do not meet this criterion, Kuttruff⁹ has proposed that Eq. (10) be used except that $\bar{\alpha}$ should be replaced with α defined as follows:

$$\alpha = -\ln(1 - \bar{\alpha}_{st})[1 + 0.5\gamma^2 \ln(1 - \bar{\alpha}_{st})] + \frac{\sum_{i=1}^n \beta_i (\beta_i - 1 + \bar{\alpha}_{st}) S_i^2}{S^2 (1 - \bar{\alpha}_{st})^2} \quad (27)$$

In Eq. (27), n is the number of room surfaces (or part room surfaces if whole surfaces are subdivided), $\bar{\alpha}_{st}$ is the statistical absorption coefficient, area averaged over all room surfaces [see Eq. (8)] and β_i is the statistical energy reflection coefficient of surface i of area S_i . The first term in Eq. (27) accounts for room dimensions that exceed the Sabine room criterion. The quantity γ^2 is the variance of the distribution of path lengths between reflections divided by the square of the mean free path length. It has a value of about 0.4 provided that the room shape is not extreme. The second term in Eq. (27) accounts for nonuniform placement of sound absorption.

Neubauer²⁴ provided an alternative modified Fitzroy equation for flat and long rooms:

$$T_{60} = \left[\frac{0.126 S_x}{\ln(1 - \bar{\alpha}_{st,x}) P_x} + \frac{0.126 S_y}{\ln(1 - \bar{\alpha}_{st,y}) P_y} + \frac{0.126 S_z}{\ln(1 - \bar{\alpha}_{st,z}) P_z} \right]^{1/2} \quad (28)$$

where P_x and P_y are the total perimeters for each of the two pairs of opposite walls and P_z is the total perimeter of the floor and ceiling. Similar definitions apply for S_x , S_y , and S_z and also for $\bar{\alpha}_x$, $\bar{\alpha}_y$, and $\bar{\alpha}_z$. Note that for a cubic room, Eq. (28) may be used with the exponent $\frac{1}{2}$ replaced by $\frac{1}{3}$.

11 POROUS SOUND ABSORBERS

11.1 Flow Resistance

The flow resistance of a porous acoustic material can be measured as described in Appendix C of Bies and Hansen.¹ Once measured, the flow resistance can be used to calculate the normal impedance of a layer

of sound-absorbing material with a rigid backing or with a cavity backing. The effect of a limp impervious protective cover and/or a perforated steel cover can also be calculated. The normal impedance can be used together with Eq. (19) to calculate the statistical absorption for each case.

The relationships between porous material flow resistivity and the characteristic impedance, Z_m , and propagation constant, k_m , that have been generally accepted^{25,26} and that are accurate in the flow resistivity range $R_1 = 10^3$ to 5×10^4 MKS rayls/m are as follows:

$$Z_m = \rho c [1 + 0.0571 X^{-0.754} - j 0.087 X^{-0.732}] \quad (29)$$

$$k_m = (\omega/c) [1 + 0.0978 X^{-0.700} - j 0.189 X^{-0.595}] \quad (30)$$

where

$$X = \rho f / R_1 \quad (31)$$

More accurate (and more complex) expressions that cover a wider frequency range are given in Appendix C of Bies and Hansen.¹

The normal impedance for a rigidly backed porous material is

$$Z_N = -j Z_m / \tan(k_m \ell) \quad (32)$$

Substituting the result from Eq. (32) into Eqs. (17) and (18), and substituting the result for β and ξ into Eq. (19) allows the statistical absorption coefficient to be calculated. Evaluation of Eq. (19) for a range of frequencies and flow resistance values results in the curves shown in Fig. 2.

11.2 Porous Materials with a Backing Cavity

The performance of a porous blanket material can be improved by mounting it so that an air gap between the material and the hard backing wall is provided. The effect of the cavity can be determined by calculating the combined normal impedance due to the cavity and the sound-absorbing material and substituting the result into Eq. (19).

For a material of infinite depth, the normal impedance is equal to the characteristic impedance of Eq. (29). For a porous blanket of thickness, ℓ , backed by a cavity of any depth, L (including $L = 0$) with a rigid back, the normal impedance (in the absence of flow past the cavity) may be calculated using an electrical transmission line analogy and is given by²⁷

$$Z_N = Z_m \frac{Z_L + j Z_m \tan(k_m \ell)}{Z_m + j Z_L \tan(k_m \ell)} \quad (33)$$

The specific normal impedance, Z_L , of a rigidly terminated, partitioned backing cavity is given by

$$Z_L = \frac{-j \rho c}{\tan(2\pi f L / c)} \quad (34)$$

Figure 2 Calculated statistical absorption coefficient for a rigidly backed porous material in a reverberant field, as a function of a frequency parameter, for various indicated values of flow resistance. The quantity R_1 is the flow resistivity of the porous material (MKS rays/m), ρ is the density of air (kg/m^3), c is the speed of sound in air (m/s), f is the frequency (Hz) of the incident sound, and ℓ is the porous material thickness (m).

and for a rigidly terminated, nonpartitioned backing cavity:

$$Z_L = \frac{-j\rho c \cos \theta}{\tan(2\pi fL/c)} \quad (35)$$

where θ is the angle of incidence of the sound wave measured from the normal to the surface. A partitioned cavity is divided into compartments by partitions that permit propagation normal to the surface while inhibiting propagation parallel to the surface of the liner. The depth of each compartment is equal to the overall cavity depth.

11.3 Porous Liner Covered with a Limp Impervious Layer

In practice, it is often necessary to protect a porous liner from contamination by moisture, dust, oil, chemicals, and the like, which would render it useless. For this reason the material is often wrapped in a thin, limp, impervious blanket made of polyurethane, polyester, aluminum, or polyvinyl chloride (PVC). The effect of the introduction of a wrapping material is generally to improve the

low-frequency absorption at the expense of the high-frequency absorption. However, if the wrapping material is sufficiently thin (e.g., 20-mm-thick polyurethane), then the effect is not measurable. The effect can be determined by calculating the combined normal impedance due to the membrane and the sound-absorbing material and substituting the result into Eq. (19).

If the porous material is protected by a covering or by enclosing it in an impervious blanket of thickness h and mass per unit area, σ' , the effective specific normal impedance at the outer surface of the blanket, Z_{NB} , which can be used together with Eq. (19) to find the absorption coefficient of the construction, is as follows:

$$Z_{NB} = Z_N + j2\pi f\sigma' \quad (36)$$

where f is the frequency of the incident sound, tone, or center frequency of a narrow band of noise. Typical values for σ' and $\sqrt{E/\rho}$ are included in Table 2 for commonly used covering materials.

Guidelines for the selection of suitable protective coverings are given by Andersson.²⁸

11.4 Porous Liner Covered with a Perforated Sheet

When mechanical protection is needed for a porous liner, it may be covered using perforated wood, plastic, or metal panels. If the open area provided by the perforations is greater than about 20%, the expected absorption is entirely controlled by the properties of the porous liner, and the panel has no effect.

Alternatively, if the facing panel has an open area of less than 20%, the statistical absorption coefficient of the panel plus sound-absorbing material can be determined by calculating the specific normal impedance of the combined construction and using the result in Eq. (19). According to Bolt²⁹ the normal impedance is

$$Z_{NP} = Z_N + \frac{(100/P)\{j\rho c \tan[k\ell(1-M)] + R_a A\}}{1 + (100/j\omega m P)\{j\rho c \tan[k\ell(1-M)] + R_a A\}} \quad (37)$$

where Z_N is the normal specific acoustic impedance of the porous acoustic material with or without a cavity backing (and in the absence of flow), ℓ is the effective length (see Chapter 9 of Bies and Hansen¹) of each of the holes in the perforated sheet, ω is the radian

Table 2 Properties of Commonly Used Limp Impervious Wrappings for Protection of Porous Materials

Material	Density (kg/m^3)	Typical Thickness ($\mu\text{m} = 10^{-6} \text{ m}$)	$\sigma' (\text{kg/m}^2)^a$	$c_L \approx \sqrt{E/\rho} \text{ (m/s)}$
Polyethylene (LD)	930	6–35	0.0055–0.033	460
Polyurethane	900	6–35	0.005–0.033	1330
Aluminum	2700	2–12	0.0055–0.033	5150
PVC	1400	4–28	0.005–0.033	1310
Melinex (polyester)	1390	15–30	0.021–0.042	1600
Metalized polyester	1400	12	0.017	1600

^a σ' and c_L are, respectively, the surface density and speed of sound in the wrapping material.

frequency, P is the percent open area of the holes, R_d is the acoustic resistance of each hole (see Chapter 9 of Bies and Hansen¹), A is the area of each hole, M is the Mach number of the flow past the holes, and m is the mass per unit area of the perforated sheet.

The frequency, f_{\max} , of maximum absorption for a perforated panel (of open area less than 20%) is given approximately by the following transcendental equation, which can be solved by trial and error:

$$(2\pi f_{\max} L/c) \tan(2\pi f_{\max} L/c) = \frac{PL/100}{t + 0.85d(1 - 0.22d/q)} \quad (38)$$

In Eq. (38), P is the percentage open area of the panel, L is the depth of the backing cavity including the porous material layer, t is the panel thickness, d is the diameter of the perforations, and q is the spacing between hole centers. If the porous material fills the entire cavity so that the thickness of the porous material is also L , then the speed of sound c should be replaced with $0.85c$ to account for isothermal rather than adiabatic propagation of sound in the porous material at low frequencies. Measured data for a panel of 10% open area are presented in Fig. 3.

11.5 Porous Liner Covered with a Limp Impervious Layer and a Perforated Sheet

In this case, the impedance of the perforated sheet and impervious layer are both added to the normal impedance of the porous acoustic material so that:

$$Z_{NBP} = Z_N + \frac{(100/P)\{jPc \tan[k\ell(1-M)] + R_d A\}}{1 + (100/j\omega m P)\{j\rho c \tan[k\ell(1-M)] + R_d A\}} + j2\pi f\sigma' \quad (39)$$

where σ' is the mass per unit area of the impervious membrane. It is important that the impervious layer and the perforated sheet are separated, using something

Figure 3 Effect of perforations on the sound absorption of a panel backed by a porous liner. The panel surface weight is 2.5 kg/m^2 and its thickness is 3 mm. The porous liner is 50 mm thick and about $5 \rho c$ flow resistance.

like a mesh spacer, otherwise the performance of the construction as an absorber will be severely degraded.

12 PANEL SOUND ABSORBERS

Porous liners are not very effective in achieving low-frequency absorption. When low-frequency absorption is required, panel absorbers are generally used. These consist of flexible panels mounted over an airspace, for example, on battens attached to a solid wall. Alternatively, such panels may be mounted on a suspended ceiling. In any case, to be effective the panels must couple with and be driven by the sound field. Acoustic energy is then dissipated by flexure of the panel. Additionally, if the backing airspace is filled with a porous material, energy is also dissipated in the porous material. Maximum absorption occurs at the first resonance of the coupled panel-cavity system.

It is customary to assign a Sabine absorption coefficient to a resonant panel absorber, although the basis for such assignment is clearly violated by the mode of response of the panel absorber; that is, the absorption is not dependent upon local properties of the panel but is dependent upon the response of the panel as a whole. Furthermore, as the panel absorber depends upon strong coupling with the sound field to be effective, the energy dissipated is very much dependent on the sound field and thus on the rest of the room in which the panel absorber is used. This latter fact makes prediction of the absorptive properties of panel absorbers difficult. A typical example of absorption coefficients for a panel absorber is shown in Fig. 3.

The following method for determining the Sabine absorption of panel absorbers is empirical³⁰ and is based upon data measured in auditoria and concert halls. The essence of the prediction scheme is contained in Figs. 4 and 5. First of all, the type of Sabine

Figure 4 Sabine absorption coefficients for resonant plywood panels. The panel configurations corresponding to the curves labeled A–J may be identified using Fig. 5. Dashed curves (G–J) represent configurations with no absorptive material in the cavity behind the panel. Configurations A–F require a sound-absorbing blanket between the panel and backing wall. The blanket must not contact the panel and should be between 10 and 50 mm thick and consist of glass or mineral fiber with a flow resistance between 1000 and 2000 MKS rays. Panel supports should be at least 0.4 m apart.

Figure 5 Design curves for resonant plywood panels to be used in conjunction with Figure 4. The quantity f_0 is the frequency at which maximum sound absorption is required.

absorption curve desired is selected from curves A to J in Fig. 4. The solid curves are for configurations involving a blanket (25 mm thick and flow resistance between $2 \rho c$ and $5 \rho c$) in the air gap behind the panel, while the dashed curves are for no blanket. Next, the frequency f_0 , which is the fundamental panel resonance frequency and the frequency at which maximum absorption is required, is determined, and Fig. 5 is entered for the chosen curve (A to J) and the desired frequency f_0 . The required air gap (millimetres) behind the panel and the required panel surface density (kilograms per square metre) are read directly from the figure. The resonance frequency used in the preceding procedure is calculated using:

$$f_0 = \frac{1}{2\pi} \sqrt{\frac{\rho c^2}{mL}} \quad (40)$$

which does not take into account the panel rigidity or geometry. A more accurate equation for a plywood panel is³¹

$$f_0 = \frac{1}{2\pi} \sqrt{\frac{\rho c^2}{mL + 0.6L\sqrt{ab}}} \quad (41)$$

where m is the mass per unit area of the panel (kilograms per square metre), L is the depth of the backing cavity, and a, b are the panel dimensions. Thus, it is recommended that before using Fig. 5, the frequency of maximum desired absorption be multiplied by the ratio:

$$f_0 = \sqrt{\frac{m}{m + 0.6\sqrt{ab}}} \quad (42)$$

CHAPTER 105

SOUND INSULATION – AIRBORNE AND IMPACT

Alfred C. C. Warnock
National Research Council of Canada
Ottawa, Ontario, Canada

1 INTRODUCTION

The control of airborne and impact sound transmission through common building elements is of considerable importance. Airborne sound originates from a source radiating sound waves into the air that then impinge on the surfaces of building elements. Examples are speech or music from a television or a loudspeaker. Impact sound is generated when some object strikes a surface of the building. The most common source of impact sound is footsteps, but there are others, such as furniture being moved and cleaning and other equipment that is operating directly on the surface of floors, stairs, and landings. Achieving good sound isolation in buildings demands careful consideration of all possible paths for sound and the junctions between walls and floors (flanking sound transmission); it is not enough to consider only the direct path through the common wall or floor. Airborne and flanking sound transmission can be estimated from theoretical considerations or determined from laboratory measurements.

2 AIRBORNE SOUND INSULATION

When sound strikes one surface of a wall, floor, or other building element, a very small fraction of the incident energy is radiated from the other side. The *sound transmission loss** (TL) is the ratio of the incident sound energy relative to the transmitted sound energy, expressed in decibels (dB).

Two-room methods for measuring sound insulation are specified in standards.^{1,2} The test specimen is mounted between reverberant source room and receiving rooms so the only significant path for sound transmission is through the specimen; transmission along other paths is suppressed. Laboratory tests allow comparison among different elements and with requirements in certain building codes. Similar test methods are available to check the degree of sound isolation achieved in buildings.^{3,4} To measure the airborne sound insulation of facade elements and facades special methods^{5,6} are used.

Introduced in 1981,⁷ sound intensity measurements to determine sound insulation have now been standardized,^{8,9} but great care is needed to obtain accurate results. Differences at low frequencies have been found^{10,11} between results from the standard two-room test procedures and those from intensity measurements.

*Sound transmission loss is also known as sound reduction index, R , in European and ISO standards.

2.1 Single-Leaf Building Elements

The transmission loss of a homogeneous, *limp*, non-porous plate for plane-wave incidence is commonly approximated by the *field incidence mass law*,¹² $TL = 20 \log mf - 47$ dB, where m is the surface mass of the plate (kg/m^2), and f is frequency (Hz).

Bending waves in panels with finite stiffness give rise to the *coincidence effect*.¹² At every frequency above a certain *critical frequency*, f_c , there is an angle of incidence for which the wavelength of the bending wave in the plate becomes equal to the wavelength of sound in air projected onto the plate; the waves coincide. Because of this effect, a region of relatively low sound insulation occurs in some frequency range in the curve of transmission loss. For example, the curve for gypsum board in Fig. 1 shows a coincidence dip with a minimum at 2500 Hz.

For a given material with thickness h , the product $f_c h$ is a constant that depends only on its physical properties. Table 1 gives values of $f_c h$ for common building materials. The resonance dip due to the coincidence effect usually begins about an octave

Figure 1 Sound transmission through some common building materials: 100-mm concrete (233 kg/m^2), 16-mm plywood (7.5 kg/m^2), and 16-mm oriented strandboard (9 kg/m^2) on joists, and 16-mm gypsum board (11.3 kg/m^2). The dashed line represents mass law predictions for 233 kg/m^2 . The numbers next to each curve are STC ratings.

Table 1 Surface Mass for 1-mm Thicknesses and Constant $f_c h$ for Some Common Building Materials

Material	Surface Mass (kg/m ² per mm)	$f_c h$ (Hz mm)
Aluminum	2.7	12,900
Concrete, dense poured	2.3	18,700
Hollow concrete block	1.1	20,900
Fir timber	0.55	8,900
Glass	2.5	15,200
Lead	11.0	55,000
Plexiglass or Lucite	1.15	30,800
Steel	7.7	12,700
Gypsum board	0.7	39,000
Oriented strand board ^a	0.6	15,000
Plywood ^a	0.5	16,000

^a These materials are orthotropic and show very broad, shallow coincidence dips. The values given estimate the frequency at the middle of the dip.

below the critical frequency; its depth depends on damping of the panel.

2.2 Single-Number Ratings

The sound transmission spectra in Fig. 1 present more information than is convenient for use in building codes. Standard methods assign a single-number rating to such spectra by means of reference curves or weighted summation procedures. *Sound transmission class*¹³ (STC) is calculated according to American Society for Testing and Materials (ASTM) E413. The *weighted sound reduction index*,¹⁴ R_w , is the International Organization for Standardization (ISO) equivalent. Figure 1 shows the STC contour fitted to the data for the concrete slab. The differences between the data points below the contour and the contour value are deficiencies. The sum of the deficiencies must be no greater than 32 dB, and no deficiency can exceed 8 dB (the 8-dB rule). The ASTM reference contour extends from 125 to 4000 Hz; the ISO R_w contour has the same shape but extends from 100 to 3150 Hz. There is no 8-dB rule in ISO 717. The numerical values of the two ratings are usually very close.

Weighted summation methods have been developed in ISO 717¹⁴ that take into account the higher importance of low frequencies in traffic noise and modern music systems. These methods produce corrections—spectrum adaptation terms—to be used in conjunction with the R_w rating. The proposed ratings are simply the change in A-weighted level for a pink noise signal and for a specific traffic noise spectrum that are supposed to pass through the specimen. The outdoor–indoor transmission class¹⁵ (OITC), also gives a transportation noise rating; it uses a different frequency range and source spectrum from the corresponding ISO standard and can differ quite significantly.

2.3 Orthotropic and Corrugated Materials

Many common building materials are not isotropic; the bending stiffness varies for different directions

along the panels. Plywood and oriented strandboard are two such materials, and they show greatly broadened coincidence dips as a result (Fig. 1). In practice, there is little that can be done economically to change to properties of common materials. Corrugating a sheet of material or adding ribs to it increases the bending stiffness in one direction. This can result in significant reductions in sound insulation. For example, a flat sheet of 0.7-mm-thick steel has an STC of 26. Corrugating the metal in two different ways gave STC values of 22 and 25, in each case with reductions of around 10 dB at the coincidence dips. Methods for estimating sound transmission through such materials are given in Ref. 12 and 16.

2.4 Single-Leaf Poured Concrete

For common thicknesses of concrete slabs, the critical frequency usually lies in the range where single-number ratings are calculated (Fig. 1). Because the coincidence effect significantly reduces the transmission loss relative to the ideal mass law values, the STC and R_w ratings are less than might be expected from considering mass only. Transmission loss for a concrete slab depends on the energy losses in the system and so can vary quite widely. For monolithic slabs, R_w or STC is given approximately by¹⁷ $37.5 \log m - 42$, where m is the mass per unit area of the slab (kg/m²). Inhomogeneous elements, such as floors and exterior masonry with large cavities, may provide lower sound insulation because of resonance effects.¹⁸ Thus, simple concrete partitions provide STC ratings from about 45 to 58. The most effective way to significantly increase STC beyond 58 is to attach additional layers of gypsum board to form a multileaf partition as discussed below.

2.5 Single-Leaf Concrete Masonry Walls

Solid and hollow-core concrete blocks are manufactured in a variety of thicknesses, core sizes, aggregates, and densities. Representative values of STC for block walls can be calculated¹⁹ from $STC = 0.51 \times \text{block weight (kg)} + 38$. (The dimensions of the block face are 190 × 390 mm.) The estimated values are only valid if the wall surfaces are properly sealed and the mortar joints well made.

Porous blocks allow sound to leak through and reduce the transmission loss. The greater the porosity, the greater the improvement when the surfaces of the block are sealed (e.g., by latex block sealer, epoxy paint, or a skim coat of plaster). Improvements of 5 to 10 in STC are common. It is enough to apply the sealant on one face of the block only. A layer of gypsum board attached directly with screws or dabs of glue to the block surface is *not* an effective seal because it is still able to vibrate as a separate layer. Even when gypsum board on studs or resilient supports is to be used to finish a block or concrete wall, the wall should be sealed. Covering a crack or some other flaw with gypsum board does not eliminate the detrimental effects of the flaw.

2.6 Double-Leaf Building Elements

When high sound insulation is required with minimum weight, the best approach is to construct a wall consisting of two solid leaves with a cavity between them. Ideally, there should be no solid connections between the two leaves; these provide a path for sound and lower the transmission loss. When properly designed, a double-leaf construction provides greater sound insulation at the important frequencies than a single leaf of the same mass per unit area.

Typical methods for reducing vibration transmission between leaves include (1) separate rows of wood studs, (2) staggered wood studs on a common sole plate, (3) staggered wood studs with resilient metal channels on one side (to reduce transmission around the periphery), (4) a single row of wood studs or load-bearing steel studs with resilient metal channels on one or both sides, and (5) non-load-bearing steel studs (typically made from 0.5-mm sheet steel). In all cases, connections to panels, even when resilient, should be minimized; the closer the spacing of studs or resilient metal channels, the lower the sound reduction.²⁰

Figure 2 shows the transmission loss through 16-mm gypsum board for four cases: (1) installed as a single sheet, (2) installed as two sheets screwed together as a single leaf, (3) installed as two sheets with a cavity between them, and (4) installed as two sheets with a cavity filled with glass fiber batts. This figure shows typical behavior for double-leaf walls with no solid connections. At the frequency marked f_r there is a dip in the transmission loss curve that reduces the sound insulation below that for the two

Figure 2 Transmission loss of double-leaf and of single-leaf gypsum board walls. The 25 ga. (0.5 mm) steel studs in the double wall are 38×65 mm deep. The sound-absorbing material is glass fiber with a thickness of 65 mm and a flow resistivity of 3600 N s/m^2 .

sheets in contact—even below that for the single sheet. The transmission loss of the double-leaf wall becomes equal to that for two sheets in contact below the resonant frequency. Above the resonance, there are very significant improvements in transmission loss relative to the curve for the two sheets in contact.

The reduced transmission loss at f_r is caused by the mass–air–mass resonance; the enclosed air acts as a spring, the gypsum board leaves are the masses. For an air-filled cavity, f_r can be calculated from

$$f_r = \frac{1}{2\pi} \sqrt{\frac{\rho_0 c^2}{d M_{\text{eff}}}} \quad (1)$$

where ρ_0 is the density of air (kg/m^3); c is the speed of sound in air (m/s); d is the distance between the inner surfaces (m); M_{eff} is the effective mass per unit area of the two layers given by $M_{\text{eff}} = (1/m_1 + 1/m_2)^{-1}$; and m_1, m_2 are the masses per unit area of the two layers (kg/m^2). For a given total mass, this frequency has its minimum value when both masses are equal. Generally, the lower f_r , the higher the STC.

Another feature to notice in Fig. 2 is the prominent dip in the transmission loss curve around 2500 Hz due to the coincidence effect. Such dips are often significant in determining STC or R_w . If two sheets of gypsum board are used on each side, the dip is less deep because of damping due to friction between the sheets. When different materials having different critical frequencies are used on each face of the wall or floor, the coincidence dips are less prominent.

Placing sound-absorbing material in the cavity of double-leaf wall or floor gives greatly improved sound insulation^{21–23}; STC ratings typically increase about 6 to 10 dB. Adding sound-absorbing material to the cavity lowers the frequency at which the mass–air–mass resonance occurs and leads to higher transmission loss values above f_r . As an approximate guide, when the wall cavity contains sound-absorbing material, multiply the frequency calculated from Eq. (1) by 0.7 to estimate the value of f_r . The sound-absorbing material also damps cross-cavity resonances. These occur at $f_1 = c/2d$ and integer multiples of this frequency.

The more sound-absorbing material in the cavity, the higher the transmission loss, but increasing the thickness has less effect than the initial addition of the material. In a series of measurements on a floor with 235-mm-deep joists, the STC increased from 50 to 53 as the thickness of glass fiber in the cavity was increased from 65 to 240 mm.²⁴ The STC for the empty cavity was 43. Changing the type of commonly used sound-absorbing materials has little effect on STC in common wall and floor constructions.

Prediction of sound transmission through double-leaf walls has been attempted by many authors using different models of varying complexity. When the two panels in a double-leaf partition are completely isolated

from each other, the empirical approach in Ref. 25 can be used to estimate transmission loss as follows:

$$TL = \begin{cases} 20 \log[(m_1 + m_2)f] - 47 & f < 2f_r/3 \\ TL_1 + TL_2 + 20 \log fd - 29 & f_r < f < f_1 \\ TL_1 + TL_2 + 6 & f > f_1 \end{cases} \quad (2)$$

where TL_1, TL_2 are the transmission losses for each leaf of the double wall measured or calculated separately. The expressions in Eq. (2) are slightly different from those in Ref. 25 and give an approximate way of dealing with the low-frequency resonances that often limit the sound insulation of lightweight double-panel walls.

Thus in a double-leaf partition, high sound insulation can be attained by (1) avoiding solid connections between the leaves, (2) selecting a high mass per unit area of the leaves, (3) selecting a deep cavity, and (4) filling the cavity with sound-absorbing material to ensure a low mass-air-mass resonance frequency. In practice, it is very difficult to construct a double-panel wall where the two panels are not connected in some way, and the sound reductions predicted by Eq. (2) are seldom achieved at high frequencies; there is often a solid connection around the edges of a partition for practical reasons.

2.7 Double-Leaf Gypsum Board Walls

Table 2 gives a few examples of measured STC values for walls constructed from wood or steel studs and fire-rated gypsum board.²⁰ The type of sound-absorbing material has only a small effect on the single-number rating.

When two sheets of gypsum board are joined using screws or dabs of glue, the bending stiffness of the double sheet is not significantly altered from that of a single sheet, and the critical frequency does not move

to a lower frequency where it might adversely affect the STC. Using two sheets is *not* the same as using a sheet twice as thick.

It is always detrimental to have shallow cavities within a wall or floor. For example, adding a single, solid, nonporous layer to one set of studs in the middle of a double-stud wall with sound-absorbing material in both stud cavities reduces the STC by about 3 to 4 dB.²⁰ A second layer added internally to the other set of studs decreases the sound insulation even more because of the small cavity in the middle of the wall.

For stud walls, even for a double-stud wall, the sound reduction is influenced by the spacing of the studs and resilient channels that support the gypsum board. Within practical limits, it is best if these are as far apart as possible. Thus a 610-mm spacing gives better results than 406-mm spacing. For double wood studs the increase in STC is about 2.²⁰

2.8 Joist Floors

The same principles outlined above control sound transmission through double-leaf floors. To avoid having the floor and ceiling layers rigidly connected usually requires resilient supports for the ceiling or separate joists. It is relatively simple to get high STC ratings with joist construction because of the large cavity depth; resilient ceiling supports and sound-absorbing material are all that is needed.^{24,26} If a concrete topping is used, STC ratings close to 70 can easily be attained. Just as in walls, small air cavities increase sound transmission, so resilient metal channels should *never* be used between layers of gypsum board in a floor or a wall.

2.9 Two-Leaf Masonry or Concrete Walls

Two-leaf masonry or concrete walls can, in principle, provide very high sound insulation.²⁷ The insulation attained is usually limited, however, by the practical difficulties of constructing two leaves that are structurally isolated. Depending on the height of a block wall, metal ties are required for structural reasons or to meet applicable building codes. Solid metal ties transmit sound energy from one leaf to the other, but ties designed to reduce sound transmission are available.

Also important is transmission of energy along the floor and ceiling, along walls abutting the periphery of the cavity wall, and through other parts of the structure. These *flanking paths* bypass the cavity wall and reduce its apparent sound insulation. Physical breaks in the floor, ceiling, and abutting walls are needed to reduce transmission along such paths. However, even if gaps are included in the design, during construction the airspace between leaves may become bridged by mortar droppings or rubble that will reduce the sound insulation. In practical installations careful design of the whole system, good supervision, and care during construction are needed for two-leaf block walls to achieve their potential.

Table 2 Approximate STC Ratings for Walls with 16-mm Fire-Rated Gypsum Board (~11 kg/m²) on Both Faces^a

	1 1	1 2	2 2
38 × 89 mm wood studs, 406 mm oc, RC(610) ^b	46	53	59
Staggered 38 × 89 mm wood studs	47	52	56
Staggered 38 × 89 mm wood studs, RC(610) ^b	51	56	62
Two rows of 38 × 89 mm wood studs, 406 mm oc	58	62	67
90 mm steel studs, 25 gauge, 406 mm oc	49	52	56
90 mm steel studs, 25 gauge, 610 mm oc	49	54	57

^a (1|1, 1|2, 2|2 indicates the number of layers of gypsum board on each face. oc = on center = spacing between stud midplanes.) All walls are about 75% filled with glass fiber. Using 13-mm gypsum board reduces the STC by 1 to 2 dB.

^b Resilient metal channels on one side, 610 mm oc.

2.10 Block or Concrete Walls with Added Gypsum Board

The sound insulation of a heavy wall is often improved by adding finishing layers of gypsum board, or something similar, supported independently on resilient mounts to form a cavity construction. Gypsum board is usually added on both sides of the wall, so the construction becomes a triple-leaf wall. Measurements on 190-mm-thick concrete block wall systems²⁸ showed the importance of avoiding small cavity depths that result in the mass–air–mass resonance being within or near the range used in calculating STC or R_w . Adding sound-absorbing material to the cavity clearly lowered the mass–air–mass resonance frequency. Adding gypsum board on both sides of the blocks caused the mass–air–mass resonance to be deeper than it was when the gypsum board was applied on just one side. When the cavity depth was only 13 mm, the STC was reduced by one point, but the detrimental effects on the sound insulation below 160 Hz were much more serious. These points are illustrated in Fig. 3. Table 3, based on this research, gives approximate expressions for estimating the improvement in STC rating, which results from the attachment of 13- or 16-mm fire-rated gypsum board to a concrete block wall.

Some concrete blocks are sufficiently porous that the cavity formed behind the gypsum board has an effective depth that is greater than the distance from the surface of the blocks to the rear face of the gypsum board; the air in the cavity penetrates the block.²⁹ This

Figure 3 Sound transmission loss through a bare 190-mm concrete block wall (STC 50) and with 16-mm gypsum board attached on 13-mm resilient metal channels, glass fiber, and gypsum board on one side—R1 (STC 54), and on both sides—R2 (STC 49). Curve Se is for gypsum board and 65-mm steel studs on both sides with empty cavities (STC 57). Curve Sf is the same system as Se with 65-mm glass fiber in the cavities (STC 72).

Table 3 Approximate Expressions for Estimating Change in STC, Δ STC, When 16-mm Fire-Rated Gypsum Board ($\sim 11 \text{ kg/m}^2$) Is Attached Resiliently to a Masonry Wall or Supported Independently in Front of It at a Distance d mm^a

Cavity absorption	Finish on	Δ STC
Empty	One side	$0.11 \times d - 1.2$
Filled	Both sides	$0.14 \times d - 2.8$
Empty	One side	$0.12 \times d + 1.9$
Filled	Both sides	$0.44 \times d - 7.4$

^aThe gypsum board is applied on one or both sides, and the cavity is either empty or filled with fibrous absorber.

lowers the mass–air–mass resonance and increases sound insulation, but the blocks themselves do not provide the full sound insulation expected from their mass. If the blocks are sealed on one face to offset this, there is no longer an increase in effective cavity depth on the sealed side, but there still is on the unsealed side; overall there can be considerable benefit.

The detrimental effects of the mass–air–mass resonance can be counteracted by including Helmholtz resonators in the cavity of a double-leaf construction.^{30–32} This may increase costs but the benefits can be substantial.

2.11 Doors

The sound insulation provided by a door depends not only on the type of door but also on installation details (including the door frame and gaskets around the perimeter). For well-sealed single doors approximate STC values are 20 (hollow core), 28 (solid core wood), and 30 (metal door). Since doors must be operable and therefore not too heavy, the sound insulation available from mass alone is limited. High insulation can be obtained, however, by the use of two doors. For best performance, the width of the airspace between the doors should be large or increased to form a vestibule whenever possible. Absorptive material in the airspace will improve sound insulation. For such double doors, the STC ranges from about 44 to 50 as their separation ranges from 70 to 230 mm. For good sound insulation, double doors must still be well sealed.

“Acoustical” doors—laboratory-tested—provide STC ratings from 35 to over 50. Installation is of critical importance in achieving high sound insulation. The rated performance will not be achieved unless the door frame is fitted into the wall to avoid cracks or hollows that could transmit sound, the gaskets are properly adjusted, and flanking transmission is avoided.

2.12 Windows

The STC rating of single sheets of glass is adversely affected by the coincidence effect; the critical frequency, f_c , for typical thicknesses of glass falls in the STC range. Some improvement can be obtained by using laminated glass—thin glass panes with an

intervening plastic layer. The use of two thin layers keeps the critical frequency fairly high and the plastic provides some damping. For single panes with thicknesses of 13 mm or less, STC (or R_w) may be calculated from $STC = 0.61t + 27.9$ for solid panes, or $STC = 0.47t + 31.5$ for laminated panes, where t is the total thickness of the pane including the lamination (mm).

To obtain an improvement in STC by using double glazed windows requires a cavity depth of about 20 mm or more. An airspace smaller than 100 mm is inadvisable if a weighted sound reduction index of more than about 40 dB is sought. The STC for double sheets of glass with an airspace between can be estimated using $STC = 12.4 + 10.8 \log(t) + 10.7 \log(d)$, where t is the total glass thickness (mm) and d is the depth of the cavity (mm). Using panes of different thickness can reduce the influence of coincidence effect and increase sound insulation. Absorption added in the cavity by lining the perimeter (reveals head and sill if possible) gives most benefit at high frequencies. Further improvements can be made using resonant cavities around the perimeter.^{30,31} More information on window glass can be found in Refs. 33 and 34.

Actual STC values obtained for commercial, operable window systems depend on effectiveness of the sealing systems, proper installation, and other details. With double windows it is even more important than with single windows to ensure proper sealing with resilient materials of high durability.

2.13 Outdoor Sound Penetration

The composite sound insulation of a building facade depends on the areas and transmission losses of the walls, windows, doors, roofs, and other elements. The sound fields incident on homes are different from those created for laboratory testing. It is best to use data collected or software created specifically to address this problem.^{35–37}

2.14 Multielement Partitions, Apertures, and Leaks

The composite transmission coefficient of a multielement partition is given by the sum of terms $\tau_i A_i / A_t$ for each component: A_i and τ_i represent the area and transmission coefficient of the i th component of the partition, and A_t is the total area of the multielement partition. The transmission coefficient for each component may be calculated using $\tau = 10^{-TL/10}$. In theory, the transmission coefficient of an opening is approximately one. For many practical cases, $\tau = 1$ is not a good approximation.^{38–40}

3 IMPACT SOUND INSULATION

3.1 Impact Sound Ratings

Impact sound is radiated from a floor into rooms below, but it also propagates horizontally, often causing significant annoyance. Impact sound transmission through floor systems is evaluated using a standard

tapping machine^{41–44} incorporating five 500-g hammers. Normalized impact sound pressure levels are collected and a reference curve is used to calculate ratings: the impact insulation class⁴⁵ (IIC) and the weighted index⁴⁶ $L_{n,w}$. These are the ratings most frequently used in building codes, and the discussion here focuses primarily on the factors that reduce them. The rating curve is identical in each standard (see Fig. 4), but there are differences in the ratings. As in the case of airborne sound, the ASTM IIC procedure does not allow any unfavorable deviation to be greater than 8 dB, and the IIC rating, like STC and R_w , increases as the impact sound insulation improves. The $L_{n,w}$ rating decreases as the impact sound insulation improves. The relationship between the two ratings is $IIC = 110 - L_{n,w}$ if the 8-dB rule has not been invoked.

Proposed New Rating Since its inception, there has been considerable debate about the usefulness of ISO tapping machine data obtained on different types of floors.^{47–50} The current version of ISO 717-2 suggests the use of a spectrum adaptation term, C_I , to deal with low-frequency noise typical of that generated below a lightweight joist floor. The actual rating suggested, $L_{n,w} + C_I$, is just the unweighted sum of the energy in the one-third octave bands from 50 or 100 to 2500 Hz minus 15 dB. This rating is expected to correlate better with subjective evaluation of the noise

Figure 4 Examples of tapping machine levels. The concrete slab is 150 mm thick. The three numbers under each legend are IIC, $L_{n,w}$, and the sum of the energy from 50 to 2500 Hz – 15 dB. The fitted IIC contour is shown for the bare concrete slab and the joist floor. The joist floor comprises 19-mm oriented strandboard, sound-absorbing material, and two layers of 13-mm gypsum board suspended on resilient metal channels. The floating floor is 22-mm parquet on 4-mm cork.

below floors,^{51,52} especially if the frequency range for the summation is extended down to 50 Hz.

Ratings for Floor Coverings The impact sound insulation of concrete floors is unsatisfactory unless improved by a soft floor covering or a floating floor. Often a designer needs to compare different floor coverings. This is virtually impossible when coverings are tested in different laboratories on different base floor structures. Standard methods^{53,54} have been developed to facilitate these comparisons.

A floor covering placed on a concrete slab causes a reduction of impact sound pressure level $\Delta L(f)$, that is, to a large extent, independent of the concrete slab on which it has been measured. Therefore to get a rating for the floor covering only, the measured values of $|\Delta L(f)|$ are added to a reference spectrum for a hypothetical reference floor.^{45,53} The resulting curve is evaluated following the standard procedures^{45,46} to get the rating for the combination. The improvement rating for the covering is the difference between the rating for the uncovered reference floor and that for the covered reference floor, ΔIIC or ΔL_w depending on which standard is being used. Note that these ratings are usually different because of the 8-dB rule in ASTM E989.⁴⁶ Note also that they do not apply when the floor covering is placed on a joist floor with a wood subfloor.

3.2 Concrete Floors

For a homogeneous reinforced concrete floor, doubling the thickness causes an improvement in impact sound insulation of about 10 dB. In practice the thickness of concrete floors only varies from about 150 to 250 mm. With no coverings or with hard finishes cemented directly to the floor, these floors are not satisfactory; the IIC ranges from about 25 to 35 and $L_{n,w}$ from about 85 to about 75 (Fig. 4 gives an example for a 150-mm-thick slab).

Ceilings suspended under concrete slabs reduce impact and airborne sound transmission to an extent that depends on the cavity depth, cavity absorption, and method of support. Reductions in impact sound pressure levels measured under a 150-mm concrete are shown in Table 4 for four cases. The same improvements were measured for transmission loss in each case. In buildings, if flanking transmission in the walls is not controlled, these improvements may not be achieved.

Soft Floor Coverings on Concrete Slabs Soft floor coverings reduce the impact sound pressure level due to the standard tapping machine beginning at a resonant frequency, f_0 , given by $5.98 \times 10^{-3} (E/h)^{1/2}$ where E is the dynamic Young's modulus of the covering (N/m) and h is the thickness of the covering (m). Improvement in impact sound insulation above the frequency f_0 is given approximately by $\Delta L(f) = 40 \log(f/f_0)$ dB. Improvements in IIC range from about 5 to 10 for thin floor coverings to more than 50 dB for the combination of a soft underpad and a carpet.

Floating Floors When a hard floor finish is desired, the most practical means of obtaining high-impact sound insulation is to use a floating floor construction. A floating floor consists of a load-distributing slab resting on a resilient support on top of the structural floor. Floating slabs may consist of concrete (about 30 to 60 mm thick) or of gypsum, asphalt, or of wooden floor boards nailed to battens. The resilient support might be a layer of rock wool, glass fiber, foamed plastics, or the like. Instead of a continuous resilient layer, an array of resilient pads may be used and the cavity between the floating slab and the structural floor filled with soft sound-absorbing material. Special attention has to be paid to avoid solid connections between the floating slab and the

Table 4 Reduction in Impact Sound Pressure Level due to Suspended Ceiling Systems.

Case ^a	ΔIIC	50	63	80	100	125	160	200	250	315	400	500
A	15	-8	-8	-8	-5	0	3	2	14	14	17	17
B	18	-5	-6	-3	-7	0	1	4	8	16	19	19
C	24	-8	-1	4	6	12	15	19	20	22	21	22
D	42	15	13	18	20	22	25	30	31	29	36	34
		630	800	1000	250	1600	2000	2500	3150	4000	5000	
A		11	16	16	12	14	15	14	15	16	16	
B		22	21	19	21	21	17	18	24	25	27	
C		23	21	19	18	20	20	22	25	26	28	
D		36	35	33	38	45	44	41	42	47	51	

^aA: A single layer of 13-mm gypsum board on resilient channels below a ribbed concrete slab. The average air gap was 57 mm. $\Delta IIC = 15$.

B: Two layers of 16-mm gypsum board suspended using steel spring and neoprene hangers. The average air gap was 65 mm. $\Delta IIC = 18$.

C: Same as B but with 38 mm of rock fiber in the cavity. $\Delta IIC = 25$.

D: Two layers of 16-mm gypsum board suspended using steel spring and neoprene hangers. 90 mm of glass fiber in the cavity. The average air gap was 150 mm. $\Delta IIC = 40$.

The same improvements apply to transmission loss.

structural floor. Resilient strips, placed around all slab edges, are necessary to avoid reduction of the impact sound insulation, caused by sound transmission from the load-distributing slab to the walls. Some thin floating floors comprise resilient layers about 4 to 12 mm thick finished with a layer of hardwood, about 12 mm thick. These can give Δ IIC values around 20⁵⁵ (Fig. 4).

A floating floor has a fundamental resonance frequency that is determined by the mass per unit area of the floating floor and the dynamic stiffness per unit area of the resilient support.⁵⁶ The latter consists of the dynamic stiffness per unit area of the material and that of the enclosed air,⁵⁷ which includes the effects of airflow resistivity.^{58,59} Above the resonance frequency, an increase in $\Delta L(f)$ of around 30 dB/decade in frequency is typical. As with other resonant systems, there can be a *decrease* in sound insulation around the resonance frequency. Procedures for estimating the reduction in impact sound pressure level resulting from the use of a floating floor are given in Ref. 60.

3.3 Joist and Truss Floors

The same factors that control airborne sound transmission are important in the control of impact sound through double-leaf floors. Ceilings should be supported resiliently to take advantage of the large cavity provided by the joists, and the cavity should have sound-absorbing material placed in it. Joist or truss floors are generally much lighter than solid concrete floors and, because of the lack of mass, transmit more impact sound at frequencies below 100 Hz, the limit for evaluating IIC and $L_{n,w}$. Figure 4 shows a typical impact spectrum for a joist floor, the ratings for which are determined primarily by the levels at low frequencies. In practice, these can only be reduced by increasing the total mass in the floor layers. Adding a resilient finish on the floor decreases high-frequency levels, but the ratings remain essentially unchanged.

The concrete slab in Fig. 4 is greatly improved at high frequencies when a light floating floor is added. Such floating floors placed on joist floors do *not* give the same improvement as on a concrete or other hard surface. In some lightweight joist systems the resilient layer gives no benefit.⁵⁵

With lightweight joist floors, the IIC or $L_{n,w}$ rating might meet all building code requirements, but occupants may still complain about low-frequency impact sound from walkers. For example, using a carpet will give high IIC or $L_{n,w}$ ratings but provides little reduction in footstep noise at low frequencies.

A common practical solution for joist construction is to use a slab of concrete or gypsum concrete resting on a resilient layer. The weight of the concrete provides increased protection against low-frequency impacts. The resilient layer reduces high-frequency transmission but, if necessary, the final floor covering can be resilient to some degree. This kind of floating floor inherently provides high STC and IIC ratings and is also an effective means of controlling flanking transmission in the subfloor.

4 FLANKING TRANSMISSION

When sound transmission is measured in a laboratory, there is, in principle, negligible transmission of sound energy along paths other than the *direct* path through the specimen. In buildings, all surfaces in both rooms may interact with the common wall to increase the net sound transmission. Sound transmission along paths other than that through the common wall or floor is called *flanking transmission*. When sound isolation is measured in a building, the level in the receiving room includes all flanking sound from all surfaces and energy from sound leaks. The energy is usually ascribed to the common partition and the quantity calculated is called the *apparent sound reduction index* or *apparent transmission loss*.

Flanking transmission can often dominate the sound isolation to the point that improvements in the primary separating element have little or no effect on the composite sound isolation. Procedures for estimating sound isolation between rooms when flanking transmission is present have been proposed^{61,62} and standardized^{17,60} in Europe. These procedures are more suited to concrete construction than wood or steel frame construction. In framed construction, the layers of material are relatively light and flanking transmission can be very serious^{63–67}; structure-borne transmission along the floor can be particularly detrimental. The use of a resiliently supported slab—40 mm or so of concrete—reduces the serious flanking that occurs when the subfloor is common to two adjacent apartments.

During the design of a building, all possible flanking paths must be considered and steps taken to minimize their effect. Otherwise, the net sound isolation can be *much less* than that expected from laboratory testing, and building code requirements may not be met. With good design of the junctions between walls and floors and the use of floating floors and resiliently supported wall and ceiling surfaces, flanking can be reduced so sound isolation ratings measured in the field are close to those obtained in the laboratory.

4.1 Acoustical Requirements in Building Codes

National building codes and standards usually contain requirements for sound insulation, aimed at meeting the demands of different functions of rooms and buildings (see Chapter 114). Often, requirements are stated in terms of laboratory measurements. This is an unsatisfactory approach. Flanking transmission can drastically reduce sound isolation between homes. For occupant satisfaction, it is better to assume that the intent of the code is to provide minimum *apparent* STC or IIC values and design accordingly to control flanking sound.

5 SOURCES OF INFORMATION ON SOUND TRANSMISSION

Many manufacturers provide collections of sound transmission data using their products. As well, other agencies have printed collections of information.^{68,69} When comparing apparently identical structures among

such publications, it is important to be sure that all details are identical. Changes in mass, screw, or stud spacing or some other detail can have a large effect on the sound transmission.

CHAPTER 106

RATINGS AND DESCRIPTORS FOR THE BUILT ACOUSTICAL ENVIRONMENT

Gregory C. Tocci
Cavanaugh Tocci Associates, Inc.
Sudbury, Massachusetts

1 INTRODUCTION

Sound in spaces, as well as the acoustical performance of materials or building elements, most often vary significantly with frequency. Easily measured, single-number quantities often do not fully characterize sound in spaces or the acoustical performance of materials. For this reason, *acoustical ratings* or *descriptors* have been developed that characterize in a single number two or more of the three fundamental characteristics of sound: (1) spectral content, (2) level, and (3) time-varying character. These are referred to as ratings or descriptors since many of them cannot be treated mathematically as simple logarithmic values such as sound pressure level or sound transmission loss. Nevertheless, ratings of all kinds have been developed and are most widely used in determining the suitability of sound in spaces or the relative performance of materials.

In speaking of sound in spaces, the term *built environment* has been used to denote that “spaces” as here considered, go beyond simple enclosed building spaces such as offices and classrooms, but are relevant to any place where sound as a signal or as a background needs to be tailored to suit the needs of a listener.

Generally, ratings for acoustical environments either set limits on background sound to achieve an acceptable venue or set requirements for audio signal levels to achieve acceptable functionality. In addition, architectural acoustical criteria set limits for sound transmission through building partition constructions, for example, outdoor sound transmitted indoors and indoor sound transmitted between rooms.

This chapter identifies descriptor and rating methods used in establishing acoustical criteria in buildings in the United States. (Descriptors and rating methods used in Europe are discussed in Chapter 114.) Many of these are defined in other chapters of this handbook; those that are, are only briefly described in this chapter.

The chapter begins with a description of common acoustical descriptors used to quantify sound in the environment. These include sound pressure level, speech interference level, equivalent sound level, and so forth. Many of these are discussed in more detail elsewhere, in particular in Chapter 34. Section 2 of this chapter discusses ratings used to quantify and characterize sound inside and outside of buildings. These include day–night average sound pressure level, noise criteria curves, and so forth. Section 3 discusses descriptors and ratings for the acoustical performance of materials and systems used in the construction

of buildings. These generally break down into two types of ratings. These are ratings used to quantify the ability of building materials to absorb sound and the ability of building materials and systems to resist the transmission of sound. Section 4 discusses descriptors used to assess the quality of sound in building spaces. The discussions draw heavily on standards and methods of the American National Standards Institute (ANSI) and American Society for Testing and Materials (ASTM).

2 GENERAL ACOUSTICAL DESCRIPTORS

2.1 A-Weighted Sound Pressure Level

The human ear is sensitive to sound extending from approximately 20 to 20,000 Hz but is most sensitive to sound in the 500- to 4000-Hz frequency range. Above and below this frequency range, in which the ear is most sensitive, the ear is progressively less sensitive to sound. Since sound measurement instrumentation is typically more uniformly sensitive to sound over a considerably wider frequency range than human hearing, sound level meters use electronic filtering to reproduce the varying sensitivity of the ear to sound at different frequencies. Using this filtering, sound level meters indicate a sound level that is more representative of what the ear hears. This filtering is called A-weighting, and sound measured using A-weighted filtering is called A-weighted sound pressure level (abbreviation, AL; letter symbol, L_A).

The A-weighted sound pressure level is often used to evaluate general human exposure to sound. The A-weighted sound pressure level is most widely used as it is a convenient single-number quantifier of sound over the audible frequency range (as discussed in Chapter 34). Originally, A-weighting was intended to represent the varying sensitivity of the ear to sound at sound pressure levels ranging between 40 and 60 dB. B- and C- weightings were intended to represent the varying sensitivity of the ear to sound over higher sound pressure level ranges. Both B- and C-weightings allow more low-frequency sound energy with C-weighting being nearly flat across the audible frequency range. However, B- and C-weightings are no longer widely used, with the exception that C-weighting is used by some agencies and researchers in assessing transient sound. Also, in the absence of spectral information (octave band sound pressure levels), the difference between A-weighted and C-weighted sound pressure levels can be used to indicate

the relative content of low-frequency energy in the sound spectrum.

2.2 Speech Interference Levels

The speech interference level (SIL) is the arithmetic average of the sound pressure level in octave bands centered at 500, 1000, 2000, and 4000 Hz.¹ SIL is also discussed in Section 7 of Chapter 34. Because the definitions and octave bands used in the past have changed, ANSI S3.14 recommends that the abbreviation SIL be followed by an indication of the octave bands used for computation, for example, SIL (0.5, 1, 2, 4). Figure 1 shows the relationship between speech interference level and vocal effort required at various distances to achieve just-reliable speech communication. The cross-hatch range indicates expectant voice level, that is, the natural inclination of speakers to raise their voices in the presence of high background sound pressure levels. The rate at which the voice is raised ranges between 3 dB and 6 dB for every 10-dB increase in the background A-weighted sound pressure level above 50 dB.

The SIL criteria presented in Fig. 1 are applicable to both indoor and outdoor environments and simply relate to speech communication, without any

Figure 1 Talker-to-listener distances for just-reliable communication. The curves show maximum permissible talker-to-listener distances for just-reliable speech communication. The parameter on each curve indicates the relative voice level. Since a talker will raise his or her voice in noise, typically at the rate of 3–6 dB for every 10-dB increase in the A-weighted noise level above 50 dB, the expected voice level will increase with increasing noise level. The cross-hatched area shows the range of permissible talker-to-listener distances under these conditions. The lower bound of the cross-hatched area is for voice level being raised at the rate of 3 dB per 10-dB increase in noise level; the upper bound is for a rate of increase of 6 dB per 10-dB increase in noise level. Instructions for use: (1) Measure the A-weighted sound pressure level of the background noise using the slow response of the sound level meter. (2) Locate this sound pressure level on the upper abscissa. (3) A perpendicular dropped from this point will intersect several curves, indicating the maximum distance between the talker and listener for just-reliable speech communication for various levels of vocal effort.

accounting for other circumstances or activities in a space.² This figure also includes instructions for its use for determining minimum vocal effort and/or maximum distance to achieve just-reliable speech articulation (articulation index of 0.45) in the presence of broadband (flat spectrum) background noise. The method is not valid for (1) situations where the background sound spectrum departs significantly from being “flat,” (2) situations where the background or the signal sound levels vary significantly with time, (3) communications in highly reverberant environments, and (4) situations when speech is distorted.

2.3 Loudness Level

The loudness level (LL) is a single-number rating expressed in units of phons. It is described more fully in Chapters 34 and 119. The loudness level in phons is the level of a 1000-Hz reference tone with a loudness that appears to be equal to that of the spectrum being rated.³ The loudness level of an octave band spectrum is obtained by a procedure described in ANSI S3.4–1980(R1986).⁴ The procedure involves overlaying an octave band spectrum of sound to be rated on contours of approximate equal loudness and interpolating loudness index values for each octave band level of the spectrum. These loudness index values are then used with specified formulas to arrive at a single-number loudness level rating in phons. Phons are a logarithmic quantity. The corresponding linear quantity is sones where 1 sone is the loudness of a sound whose loudness level is 40 phons. A doubling of amplitude in sones corresponds to a factor of 10 increase in loudness level expressed in phons.

2.4 Equivalent Sound Pressure Level

As discussed in Chapters 34, 125, and 127, the equivalent sound pressure level (QL; symbol, L_{eq}) is the energy average sound pressure level occurring at a particular location over a given time interval. The equivalent sound pressure level is also discussed in Section 9 of Chapter 34. Often, the ambient sound pressure level is monitored for 1-h intervals for environmental sound assessments. When appropriate, hourly equivalent sound pressure levels may be combined in order to determine the equivalent sound pressure level for a 24-h period, or equivalent sound pressure levels for shorter time intervals can be combined to determine the hourly equivalent sound pressure level. Most often, the equivalent sound pressure level is an A-weighted sound pressure level, and the L_{eq} symbol implies A-weighting. Some agency criteria incorporate the C-weighted equivalent sound pressure level, symbolized as L_{Ceq} .

2.5 Sound Exposure Level

The sound exposure level (SEL; symbols, L_{ET} or L_{AE}) quantifies the total A-weighted sound energy integrated over a time interval for a given acoustical event. To simplify the units to decibels, the SEL of an event is described as the hypothetical equivalent sound pressure level enduring for a period of one second that would have the same amount of acoustic energy as the

specific transient event for which the SEL was measured. The SEL is used to quantify the sound energy associated with a transient event such as an aircraft over flight. Its practical use requires setting a measurement start and a finish time, but if the maximum sound pressure level occurring during an event is high enough in amplitude compared to levels before and after the event, defining precise start and finish times has little influence on the SEL value reached.

2.6 Single-Event Noise Exposure Level

The single-event noise exposure level (SENEL) is similar to the SEL except that it incorporates the integration of sound energy from and to defined points in time before and after a transient event. These points in time are defined as the moments during which the event sound pressure level rises above and falls below a specific sound pressure level threshold. For environmental sound analysis, a commonly used threshold is an A-weighted sound pressure level of 65 dB. This threshold is not set by any standard, but by measurement personnel seeking a clear point at which the sound pressure level associated with a transient event is sufficiently above the ambient so that lesser transients in the ambient do not trigger an SENEL event. The concept of SENEL has its roots in instrumentation developed to measure transient events from sources such as aircraft and trains.

In other chapters of this handbook, most particularly Chapters 34, 119, 125, and 127, A-weighting, speech interference level, loudness level, equivalent sound level, sound exposure level, and single-event noise exposure level are discussed. Certain of these do not have direct bearing on current criteria and standards but are sometimes used in data analysis. For example, the SEL and SENEL are sometimes used to determine the day–night exposure level at building sites produced by transient events such as trains or aircraft. In the 1960s, sound produced by building mechanical equipment was often expressed in sones (loudness level). Despite the current use since the 1970s of sound power level and sound pressure level at reference distances, sones are sometimes still used by certain manufacturers for quantifying sound produced by their equipment.

2.7 Percentile Sound Pressure Levels

Percentile sound levels ($L_{XX\%}$) are A-weighted sound pressure levels exceeded an indicated (by the $XX\%$ value) percent of a time interval. Percentile sound levels are also discussed in Section 11 of Chapter 34. Strictly speaking, the descriptor should also indicate the interval length, for example, $L_{90}(1\text{ h})$. The $L_{90}(1\text{ h})$ is the A-weighted sound pressure level exceeded a total of 54 min out of a continuous 60-min interval. Accordingly, the $L_{10}(20\text{ min})$ is the A-weighted sound pressure level exceeded 2 min out of a continuous 20-min interval.

The L_{10} is representative of intrusive sounds, sounds of short duration, but high level. The L_{90} , on the other hand, is representative of nearly the lowest levels of sound occurring during quiet interludes and is often referred to as the background or residual sound level.

The U.S. Federal Highway Administration (FHWA) has developed guidelines for evaluating the impact of highway noise for adoption by state highway agencies. These guidelines allow the alternative use of L_{10} or L_{eq} (one or the other, but not both) for assessing traffic sound levels and uses these descriptors to set guideline limits for traffic noise exposure at wayside areas according to various categories of land use.⁵

Some states and municipalities in the United States set environmental noise limits based on percentile sound level limits. For example, the Commonwealth of Massachusetts Department of Environmental Protection requires that sound generated by a commercial facility may not cause an ambient noise level that exceeds the preexisting background A-weighted sound pressure level (L_{90}) without the facility operating by more than 10 dB.⁶ The City of Cambridge, Massachusetts, requires that construction 10-percentile sound pressure levels $L_{10}(20\text{ min})$ should not exceed 75 dB at the nearest residential property.⁷

3 RATINGS USED TO ASSESS THE ACCEPTABILITY OF AMBIENT SOUND

3.1 Day–Night Average Sound Level

The day–night average sound pressure level (DNL; symbol, L_{dn}) is a 24-h average A-weighted sound pressure level where a 10-dB “penalty” is applied to sound occurring between the hours of 10:00 p.m. and 7:00 a.m. The 10-dB penalty accounts for the heightened sensitivity of a community to noise occurring at night. This descriptor is also discussed in Section 10 of Chapter 34. Day–night average sound pressure level has become the primary descriptor for general environmental sound in the United States and is often used to assess sound from transportation systems. Among agencies using the day–night average sound pressure level in their criteria and regulations are the U.S. Environmental Protection Agency (EPA),⁸ the Federal Aviation Administration (FAA),⁹ and the U.S. Department of Housing and Urban Development (HUD).¹⁰

The U.S. EPA has taken the lead among all federal agencies in unifying usage of environmental sound pressure level descriptors. The EPA has promoted the development of the day–night average sound pressure level but has not enacted regulations controlling general environmental noise. Instead, it has issued guidelines that identify yearly DNL “sufficient to protect public health and welfare from the effects of environmental noise.” Table 1 presents EPA’s suggested levels to protect public health and welfare. The EPA specifically cautions that these tabulated levels are not to be used as regulations by other agencies without addressing economic and other considerations associated with sound level restrictions. Of these levels, the most widely cited are a day–night average sound pressure level of 55 dB for outdoor residential areas and a day–night average sound pressure level of 45 dB for indoor residential spaces. Again, these are only to be used as levels with a margin of safety incorporated and not as EPA’s recommendations for agency limits.

Table 1 Yearly DNL Values That Protect Public Health and Welfare with a Margin of Safety

Effect	Level	Area
Hearing	$L_{eq}(24) \leq 70$ dB	All areas (at the ear)
Outdoor activity interference and annoyance	$L_{dn} \leq 55$ dB	Outdoors in residential areas and farms and other outdoor areas where people spend widely varying amounts of time and other places in which quiet is a basis for use
	$L_{eq}(24) \leq 55$ dB	Outdoor areas where people spend limited amounts of time, such as school yards, playgrounds, etc.
Indoor activity interference and annoyance	$L_{dn} \leq 45$ dB	Indoor residential areas
	$L_{eq}(24) \leq 45$ dB	Other indoor areas with human activities such as schools, etc.

3.2 Community Noise Equivalent Level

The community noise equivalent level (CNEL) is similar to the DNL except that, in addition to the 10-dB penalty applied between the hours of 10:00 p.m. to 7:00 a.m., there is a 5-dB penalty applied to sound between the hours of 7:00 p.m. and 10:00 p.m. CNEL is defined in Chapter 34. Use of this descriptor seems to be declining nationally but is most commonly used in California standards, where it is allowed as an alternative environmental sound pressure level descriptor to the day–night average sound pressure level for assessing environmental sound transmission into building spaces.¹¹ It is also used to assess community noise, in particular, near airports (Chapter 125).

3.3 Noise Criterion Curves

Speech interference level and loudness level are not widely used to evaluate ambient sound in building acoustics. More widely used descriptors are noise criterion (NC) curves. The curves are designed to allow satisfactory speech intelligibility or acoustical comfort in enclosed spaces. They are based on extensive interviews of workers in various noise environments and simultaneously measured octave band noise levels.¹² Noise criterion curves are a simpler alternative to the evaluation of perceived loudness than the loudness level computation procedure. NC curves are also discussed in Section 8 of Chapter 34. Figure 2 contains the set of NC curves.¹³ The NC curves are smoothed versions of the loudness level index curves. The NC value shown for each curve is the SIL (600 to 1200, 1200 to 2400, and 2400 to 4800 Hz), that is, in the “old” octave bands, for each curve. Beranek slightly redefined these curves for the preferred octave bands and listed them in tabular form. The definitions of fifth NC increment curves beginning with NC 15 are given in Table 2.¹⁴

Often, the NC rating of a spectrum is considered within a limited frequency range, such as 500 to 4000 Hz for speech intelligibility or 63 to 125 Hz for low-frequency “rumble”-type sound levels, typically associated with heating, ventilation, and air-conditioning (HVAC) systems.

It should also be noted that NC curves are generally used in evaluating continuous sound inside building spaces produced by mechanical systems or

Table 2 NC Curve Definitions¹⁴

NC	Octave Band Frequencies in Hz								A
	63	125	250	500	1000	2000	4000	8000	
70	83	79	75	72	71	70	69	68	77
65	80	75	71	68	66	64	63	62	72
60	77	71	67	63	61	59	58	57	67
55	74	67	62	58	56	54	53	52	63
50	71	64	58	54	51	49	48	47	58
45	67	60	54	49	46	44	43	42	53
40	64	56	50	45	41	39	38	37	49
35	60	52	45	40	36	34	33	32	44
30	57	48	41	35	31	29	28	27	40
25	54	44	37	31	27	24	22	21	36
20	51	40	33	26	22	19	17	16	31
15	47	36	29	22	17	14	12	11	27

environmental sound transmitted into building spaces. Guidelines for assessing the acceptability of sound in buildings generally presume that the background sound does not have tonal or temporal characteristics that lend a distinctive feature to sound, such as transformer hum or fan blade passage tones. Using these criteria to evaluate tonal noise may not be appropriate as it may underestimate the interference of sound on occupant use of spaces.

In the United States background sound in building spaces produced by mechanical systems is not limited by any specific regulation or agency. Instead, the building design profession has, through various organizations, established design criteria for noise in architectural spaces. The two most commonly used criteria are the design guidelines for HVAC system noise in unoccupied spaces established by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) and American National Standards Institute (ANSI) S12.2-1995 Criteria for Evaluating Room Noise. For most of the many years that ASHRAE has published recommended design criteria for spaces, it has expressed them as acceptable ranges of NC curves.

In the 1980s, ASHRAE introduced a new set of curves called room criterion (RC) curves, which are discussed below. On their first introduction, ASHRAE publications suggested that RC curves *could* be used

Figure 2 Noise criterion curves.

in lieu of NC curves. As the years progressed, the use of RC curves was cited as *preferred* to the use of NC curves. In the 2003 *ASHRAE Applications Handbook*¹⁵ recommended ranges of background sound in building spaces are expressed *only* as ranges of RC(N) curves (p. 47.29). The 2003 *ASHRAE Applications Handbook* states (footnote b, Table 34, page 47.29), “When quality of sound in the space is important, specify criteria in terms of RC(N). If quality of sound in the space is of secondary concern, the criteria may be specified in terms of NC or NCB levels of similar magnitude.”

Although RC curves represent a better quality of background sound, NC curves are still in wider use at this time as they represent an acceptable compromise between economy and quality of background sound. As a result, the 2005 edition of the *ASHRAE Fundamentals Handbook*¹⁶ presents several methods. These include A-weighting, NC, RC, RC Mark II, and NCB (balanced noise criteria) rating methods. The 2005 *ASHRAE Fundamentals Handbook* indicates (page 7.17) that the RC Mark II method is recommended by ASHRAE, presumably conditioned by the above-mentioned table

footnote b in the 2003 *ASHRAE Applications Handbook*. Table 3 presents the ASHRAE recommended design guidelines for HVAC system noise in unoccupied spaces. These are expressed in RC(N) levels. For use with NC curves, substituting NC levels equal to the RC levels shown is generally acceptable, subject to the cautionary footnote b in Table 3.

3.4 Room Criterion Curves

ASHRAE has adopted the use of room criterion (RC) curves for evaluating the background sound in building spaces produced by mechanical systems. These curves have undergone some refinements¹⁷ and a new auxiliary descriptor, quality assessment index (QAI), has been added. The revised curves together with the QAI descriptor comprise what is now called the RC Mark II method. Unlike NC curves, RC curves are straight lines, as shown in Fig. 3. The Mark II RC curves differ slightly from the original curves in that they are flat below 31 Hz. These curves are used by superposing them on a measured octave band spectrum.

The RC value of the spectrum is determined through the following procedure:

Table 3 Design Guidelines for HVAC-Related Background Sound in Rooms

Room Types	RC(N) (QAI \leq 5 dB) ^{a,b}
Residences, Apartments, Condominiums	25–35
Hotels/Motels	
Individual rooms or suites	25–35
Meeting/banquet rooms	25–35
Corridors, lobbies	35–45
Service/support areas	35–45
Office Buildings	
Executive and private offices	25–35
Conference rooms	25–35
Teleconference rooms	25 (max)
Open-plan offices	30–40
Corridors and lobbies	40–45
Hospitals and Clinics	
Private rooms	25–35
Wards	30–40
Operating rooms	25–35
Corridors and public areas	30–40
Performing Arts Spaces	
Drama theaters	25
Concert and recital halls ^c	
Music teaching studios	25
Music practice rooms	30–35
Laboratories (with Fume Hoods)	
Testing/research, minimal speech communication	45–55
Research, extensive telephone use, speech communication	40–50
Group teaching	35–45
Church, Mosque, Synagogue	
General assembly with critical music programs ^c	25–35
Schools ^d	
Classrooms	25–30
Large lecture rooms (without speech amplification)	25–30
Libraries	25
Courtrooms	30–40
Unamplified speech	25–35
Amplified speech	30–40
Indoor Stadiums, Gymnasiums	
Gymnasiums and natatoriums ^e	45–55
Large seating-capacity spaces with speech amplification	45–55

^a Values and ranges are based on judgment and experience, not on quantitative evaluations of human reactions. They represent general limits of acceptability for typical building occupancies. Higher or lower values may be appropriate and should be based on a careful analysis of economics, space usage, and user needs.

^b When quality of sound in the space is important, specify criteria in terms of RC(N). If quality of sound in the space is of secondary concern, the criteria may be specified in terms of NC or NCB levels of similar magnitude.

^c An experienced acoustical consultant should be retained for guidance on acoustically critical spaces (below RC 30) and for all performing arts spaces.

^d Some educators and others believe that HVAC-related sound criteria for schools, as in previous editions of this table, are too high and impede learning for affected groups of all ages. See ANSI *Standard* S12.60-2002 for classroom acoustics and a justification for lower sound criteria in schools. The HVAC component of total noise meets the background noise requirement of that standard if HVAC-related background sound \leq RC 25(N).

^e RC or NC criteria for these spaces need only be selected for the desired speech and hearing conditions.

1. Determine the midfrequency average level (L_{MF}). This is the arithmetic average, to the nearest whole number, of the sound pressure levels in the 500-, 1000-, and 2000-Hz octave frequency bands. This is the RC rating associated with the room sound pressure level spectrum.
2. Draw a line having a -5 dB/octave slope through the RC level at 1000 Hz determined from step 1.
3. Classify the subjective spectral balance of the room sound pressure level spectrum as follows:
 - a. *Neutral*. A spectrum classified as neutral is free of tonal quality and would be perceived as unobtrusive or bland. A neutral sound spectrum falls exactly along or close to a single RC contour. If the octave band data do not exceed the RC curve determined in step 2 by more

Figure 3 Room criterion curves plus examples of RC 42(N) and RC 32(R) sound pressure level spectra.

than 5 dB at and below 500 Hz and do not exceed the RC curve by more than 3 dB at and above 1000 Hz, the spectrum is considered neutral, and the designator (N) is placed after the RC level.

- b. *Rumble.* A sound spectrum that is perceived to have a “rumbly” quality has an excess of low-frequency sound energy. A rumbly spectrum is characterized as one with octave band sound levels that exceed the RC curve determined in step 2 by more than 5 dB at and below 500 Hz. For such spectra the designator (R) is placed after the RC level.
- c. *Hiss.* A sound spectrum that is perceived to have a “hissy” quality has an excess of high-frequency energy. A hissy spectrum is characterized as one with octave band sound levels that exceed the RC curve determined in step 2 by more than 3 dB above 500 Hz. For such spectra, the designator (H) is placed after the RC level.
- d. *Acoustically Induced Perceptible Vibration.* The cross-hatched region of the RC curves in Fig. 3 indicates sound pressure levels in the 16- to 63-Hz octave bands at which perceptible vibration in building walls and ceilings can occur. These sound levels often produce rattles in cabinets, doors, pictures, lighting fixtures, and so forth. For spectra with levels that fall into this range, the designator (RV) is placed after the RC level.

Figure 3 also provides examples of two types of spectra. In one case, the spectrum follows along the RC 42 curve (i.e., the average of the sound pressures in the 500-, 1000-, and 2000-Hz octave bands is 42 dB).

In this spectrum, all of the octave band levels are within the prescribed limits, and is therefore designated an RC 42(N) spectrum. The spectrum labeled RC 32(R) is generally 10 dB lower than the RC 42(N) spectrum, except in the low frequencies where the 63-Hz octave band exceeds the RC 32 contour by 6 dB, thus constituting a low-frequency rumble component.

Once, having determined the RC rating and the spectral balance characteristic of a spectrum (i.e., neutral, rumbly, or hissy), the QAI can then be determined using the following three steps.

Step 1 is to determine the RC rating using the L_{MF} as previously discussed. For convenience, this curve should be plotted together with the spectrum or listed in a table as discussed below.

Step 2 is to calculate the energy-average spectral deviations in each of the three previously mentioned frequency regions. These are as follows:

$$\Delta LF = 10 \log \left(\frac{10^{\Delta L_{16}/10} + 10^{\Delta L_{31}/10} + 10^{\Delta L_{63}/10}}{3} \right)$$

$$\Delta MF = 10 \log \left(\frac{10^{\Delta L_{125}/10} + 10^{\Delta L_{250}/10} + 10^{\Delta L_{500}/10}}{3} \right)$$

$$\Delta HF = 10 \log \left(\frac{10^{\Delta L_{1000}/10} + 10^{\Delta L_{2000}/10} + 10^{\Delta L_{4000}/10}}{3} \right)$$

In the above relationships, the ΔL_f values are the differences between the spectrum value and the RC curve value at that frequency.

Step 3 is to determine the quality assessment index (QAI). The QAI is the difference between the highest and lowest energy-average spectral deviations. If the QAI is less than or equal to 5 dB, then the spectrum is presumed to be neutral, that is, the spectrum exhibits proper balance between low-, mid-, and high-frequency ranges. Accordingly, the qualitative descriptor following the RC rating would be (N). If the QAI is greater than 5 dB, then the qualitative descriptor would be determined by the maximum energy-average spectral deviation and signified (LF), (MF), or (HF). If the spectrum exceeds the moderate or clearly noticeable criteria, the qualitative descriptors (LV_A) or (LV_B) would also be used. It is possible that two descriptors would be needed, that is, one of (N), (LF), (MF), or (HF) and one of (LV_A) or (LV_B).

Using the above three-step process, the QAI for the RC 32 spectrum of Fig. 3 has been computed in the worksheet presented in Table 4. The following is a brief explanation of the worksheet in Table 4.

Line 2 is the measured or calculated sound pressure level spectrum.

Line 3 is the L_{MF} , the arithmetic average of sound pressure levels at 500, 1000, and 2000 Hz and is also the RC Mark II rating of the spectrum.

Table 4 RC Mark II Rating and QAI Worksheet

Line	Column 1	2	3	4	5	6	7	8	9	10	11	12	13
		Octave Band Frequencies (Hz)											
1		16	31	63	125	250	500	1000	2000	4000	8000	16000	A

18	LFV _B	65	65	70									
19	$L_p - LFV_B$	-3	-5	-12	-3								

Line 4 is the corresponding neutral RC curve.

Line 5 includes the three band groupings centered in each three-band set.

Line 6 lists the arithmetic differences between the spectrum and the RC curve values in each frequency.

Line 7 includes the energy-average spectral deviation factors.

Line 8 is the arithmetic difference between the highest and lowest energy-average spectral deviation factors and is the QAI.

Line 13 is the clearly noticeable vibration criterion.

Line 14 is the arithmetic difference between the measured spectrum levels of line 2 and the clearly noticeable vibration criterion of line 13.

Line 18 is the moderately noticeable vibration criterion.

Line 19 is the arithmetic difference between the measured spectrum levels of line 2 and the clearly noticeable vibration criterion of line 18.

Table 5 presents a summary of the RC Mark II rating for the RC 32 spectrum shown in Fig. 3 and entered into Table 4. A copy of a Microsoft Excel spreadsheet to perform the RC Mark II computations for a given spectrum is available from the ASHRAE technical committee on sound and vibration (TC 2.6).

Having determined an RC Mark II rating, Blazier¹⁷ provides a means to determine how a room occupant might respond to a given spectrum. Occupant subjective responses are indicated "acceptable," "marginal," and "objectionable." These responses presume that the RC rating (which is the L_{MF}) is consistent with recommendations for such ratings on the basis of space use. The subjective responses are provided in Table 6.¹⁷

Table 5 Summary of QAI Computation for RC 32 Spectrum of Figure 3

RC Mark II Evaluation Summary	
RC neutral curve	32
A-weighted sound pressure level (dB)	41
LFVB or LFVA or neither?	0
<i>Energy-average spectral deviations</i>	
LF	4.8
MF	1.8
HF	-1.3
<i>Quality Assessment Index</i>	
QAI	6.1
Qualitative descriptor	LF
Spectrum RC Mark II Rating	RC 32(LF)

According to data in Table 5, the spectrum analyzed in Table 4 is neutral in character and has a QAI of 6.1. Since the spectrum predominates in the low-frequency range (LF) and the QAI is greater than 5 dB, the sound represented by the spectrum should be perceived as marginally acceptable as long as the RC 32 rating is appropriate for the space in which it occurs.

3.5 Balanced Noise Criterion Curves

Beranek^{18,19} has drawn upon low-frequency hearing considerations to extend NC curves down to low frequencies. He has also sloped downward the high-frequency ends of the NC curves to reduce the subjectively hissy nature of sound spectra that conform to NC spectra shapes, thereby creating a "balanced" spectrum subjectively perceived as more uniform

Table 6 Interpretation of RC Mark II Ratings Presuming Spectra Are Appropriate for Space Use¹⁷

Sound Quality Descriptor	Subjective Perception	QAI	Occupant Response
(N) Neutral	Balanced, no one frequency range dominates	$QAI \leq 5 \text{ dB}$ ($L_{16}, L_{31.5} \leq 65 \text{ dB}$)	Acceptable
(LF) Rumble	Low-frequency range dominant (16–63 Hz)	$\leq 5 \text{ dB}$ ($L_{16}, L_{31.5} > 65 \text{ dB}$) $5 \text{ dB} < QAI \leq 10 \text{ dB}$	Marginal Marginal
(LFV _A) Rumble, perceptible surface vibration	Low-frequency range dominant (16–63 Hz)	$QAI > 10 \text{ dB}$ $QAI \leq 5 \text{ dB}$ ($L_{16}, L_{31.5} > 75 \text{ dB}$)	Objectionable Marginal
(LFV _B) Rumble, perceptible surface vibration	Low-frequency range dominant (16–63 Hz)	$5 \text{ dB} < QAI \leq 10 \text{ dB}$ $QAI > 10 \text{ dB}$ $QAI \leq 5 \text{ dB}$ ($L_{16}, L_{31.5} > 65 \text{ dB}$)	Marginal Objectionable Marginal
(MF) Roar	Mid-frequency range dominant (125–500 Hz)	$5 \text{ dB} < QAI \leq 10 \text{ dB}$ $QAI > 10 \text{ dB}$ $5 \text{ dB} < QAI \leq 10 \text{ dB}$	Marginal Objectionable Marginal
(HF) Hiss	High-frequency range dominant (1000–4000 Hz)	$QAI > 10 \text{ dB}$ $5 \text{ dB} < QAI \leq 10 \text{ dB}$ $QAI > 10 \text{ dB}$	Objectionable Marginal Objectionable

and devoid of significant tonal content. A set of balanced noise criterion curves (NCBs) are presented in Fig. 4. NCB curves are also discussed in Section 8 of Chapter 34. As with RC curves, NCB curves are accompanied by a procedure for assessing the perceived balance of a sound spectrum, that is, whether or not a spectrum will be perceived as neutral, rumble, or hissy. This procedure is much like that used with the RC curves, including the use of designators (N), (R), (H), and (RV) following the BNC rating. Rules for assessing rumble and hissy qualities of sound spectra using NCB curves are as follows:

1. Determine the PSIL for the spectrum being evaluated. The PSIL is the arithmetic average of sound levels in the 500-, 1000-, 2000-, and 4000-Hz octave bands rounded to the nearest decibel, for example, XX. This spectrum would then be denoted an NCB-XX spectrum.
2. The spectrum will be perceived as rumble if any octave band sound pressure level at or below 1000 Hz is above the NCB-YY curve. YY is equal to the XX value in step 1 plus 3 dB.
3. The spectrum will be perceived as hissy if any octave band sound pressure level at frequencies above 500 Hz exceeds the NCB-ZZ curve. To determine the value ZZ, first determine the arithmetic average of sound pressure levels in the three octave bands 125 through 500 Hz. Then determine which NCB curve has this sound pressure level at 250 Hz. This is the NCB-ZZ curve.

Figure 4 also illustrates the evaluation of a spectrum using NCB curves. The example spectrum is the lower of the two spectra shown in Fig. 3 used to illustrate the use of RC curves. Note that using the NCB curves, this spectrum exhibits rumble characteristics in the 63-, 125-, and 500-Hz octave bands where octave band

sound levels exceed the NCB 29 curve by more than 3 dB.

4 DESCRIPTORS AND RATINGS FOR MATERIALS AND BUILDING CONSTRUCTIONS THAT AFFECT SOUND INSIDE BUILDING SPACES

4.1 Sound Absorption Coefficient

The ability of a material to absorb sound is characterized by the sound absorption coefficient (α). This is the ratio of the amount of sound energy absorbed to the amount incident on the surface of a sound-absorbing material. Theoretically, this can range between 0 and 1.0. The higher the sound absorption coefficient the better the ability of the material to absorb sound. Normally, materials considered to be sound absorbing have sound absorption coefficients greater than or equal to 0.5 (i.e., 50%). Because sound-absorbing materials have differing sound absorption performances at different frequencies, sound absorption coefficients are generally determined via measurements and reported in octave band frequencies—generally 125, 250, 500, 1000, 2000, and 4000 Hz. Sound absorption coefficient can be measured in a reverberation chamber²⁰ or in an impedance tube using any one of a variety of specified mounting methods.²¹ Mounting methods, especially clearance between the material and hard backing surface (reverberation room walls, floor, or ceiling) can affect the measured sound absorption coefficient significantly.

It should be noted that there are two different approaches to measuring sound absorption coefficient. The Sabine absorption coefficient is derived from the measurement of the decrease in reverberation time when an absorptive material is mounted in a reverberation chamber. A reverberation chamber is a large room built with hard, sound reflective surfaces. The reverberation time, as discussed below, is the time it takes

Figure 4 Balanced noise criterion curves for occupied rooms. Octave-band sound pressure levels of the magnitudes indicated in regions A and B may induce audible rattles or feelable vibrations in lightweight partitions and ceiling constructions (e.g., thin plaster or gypsum board on metal framing) as follows: region A, clearly noticeable vibrations; region B, moderately noticeable vibrations. (From Ref. 13.)

for the sound pressure level in the room to decay by 60 dB. This technique for quantifying absorption coefficient is best applied to relative reflective materials, though in practice the method is widely used to evaluate sound absorption coefficient of materials over the full range of sound absorption coefficient. Using this method to evaluate sound absorption coefficient tends to overestimate α for materials with relative high sound absorption coefficients.

The random incidence sound absorption coefficient, also referred to as the statistical absorption coefficient, is derived mathematically from measurements of sound absorption using an impedance tube. An impedance tube is a circular or rectangular tube with cross-sectional dimensions much smaller than the shortest wavelength to be measured. The length of the tube is longer than the first null determined by drawing the microphone probe away from the surface of the sound absorption material. A sound absorption material sample is placed at the closed end of the tube. A loudspeaker at the opposite end produces a pure tone that creates a standing wave. The distance of the standing-wave null from the surface of the material is used to calculate the normal absorption coefficient of the material. From this, the random sound absorption coefficient is computed.²²

The Sabine and random sound absorption coefficients are similar in that both are defined for a reverberant sound field in which energy is uniformly incident on surfaces from all directions. Moreover, Sabine and random sound coefficients are virtually identical for

surfaces with sound absorption coefficients of 0.1 or lower, that is, for surfaces that are mostly reflective.

The Sabine and random sound absorption coefficients differ in that the Sabine absorption coefficient is determined through an experiment by which it is measured. The analysis of the experimental data uses the Sabine reverberation formula which has three presumptions. These are that the total sound absorption in the room is the sum of the absorptions of individual surfaces, all surfaces have nearly the same absorption coefficient, and the sound absorption coefficient is small. On the other hand, the random incidence absorption coefficient is predicted from the knowledge of the absorption coefficient for a particular direction of incidence.

Use of the random incidence absorption coefficient generally produces better results in large auditoria. This is since in large auditoria two Sabine formula assumptions are often not met. These are that all surfaces have about the same sound absorption and that all surface absorptions are small. Large auditoria most often have seating areas that are much more sound absorptive than other surfaces. (For more information, refer to Lam.²²)

4.2 Noise Reduction Coefficient

To simplify comparison between sound-absorbing materials, a single-value descriptor called the noise reduction coefficient (NRC)²⁰ is used. It is the arithmetic average of the sound absorption coefficients at 250, 500, 1000, and 2000 Hz rounded to the nearest 0.05. Generally, for sound-absorbing materials, the

NRC falls between 0.55 and 0.95. Again, the higher the NRC, the higher the sound absorption performance of a material. Table 7 presents octave band sound absorption coefficients and the corresponding noise reduction coefficients for the common building materials listed.

Often, the sound absorption of building components, such as upholstered chairs in an auditorium or room sound absorption devices sold as units, are quantified in sabins, either metric (square metres) or English (square feet). This is the case for chairs, pews, and seated audience in Table 7. One sabin is an amount of room absorption equivalent to one square foot (or one square meter in metric units) of material having a sound absorption coefficient of 1.0.

4.3 Noise Reduction

The sound transmission loss (TL) of a material or building construction element is measured in a laboratory under specific conditions generally not typical of

how these materials or constructions are used in actual buildings.²³ The TL is related to the noise reduction (NR), which is the arithmetic difference between the one-third octave band sound pressure levels measured in the source and receiver rooms. In actual field conditions, which generally do not conform to minimum required laboratory conditions, the NR is measured and no attempt is made to adjust it to approximate the TL measured in a laboratory.²⁴ Instead, the NR is used and the sound transmission class (STC) rating method as described below is applied to the NR data.²⁵ The result as explained below is the noise insulation class (NIC) rating.

Noise reduction is influenced by mass, stiffness, and damping but also by the surface area size of the partition and the acoustical conditions of the source and receiver rooms. Noise reduction is not only related to the ability of a wall construction to resist the transmission of sound, but it is also related to the size

Table 7 Sound Absorption Coefficients of General Building Materials and Furnishings

Material	Sound Absorption Coefficient (α)						NRC
	125 Hz	250 Hz	500 Hz	1000 Hz	2000 Hz	4000 Hz

^aValues given are in sabins per square foot of seating area or per unit. (oz/yd² = 0.034 kg/m²; ft² = 0.0929 m².)

of the transmitting wall and the reverberant character of the receiver room. Hence, a wall construction used in different circumstances may result in different noise reductions. Most importantly, noise reduction is significantly affected by the quality of construction, specifically with respect to sound leakage paths associated with gaps and penetrations in the construction, including the perimeter of doors and windows, electrical outlets, fixtures, ductwork, and so forth.

4.4 Sound Transmission Loss

Sound transmission loss is 10 times the logarithm of the ratio between the sound energy incident on a material or sound isolation construction, divided by the sound energy transmitted through this material, and is expressed in decibels. Unlike noise reduction, sound transmission loss is measured in a laboratory according to standards established in ASTM E90.²³ The standard requires that sound transmission loss be measured in one-third octave frequency bands in a source room–receiver room test suite that complies with certain standards of sound isolation and room dimensions. The result of the test standard is a one-third octave band sound transmission loss spectrum extending from 100 (80 optionally) to 5000 Hz.

Unlike noise reduction, the TL is influenced only by mass, stiffness, and damping and how a construction is configured. Specifying the performance of a wall construction in terms of TL is more logical in that TL is only influenced by characteristics directly related to properties of the material or wall construction type.

4.5 Sound Transmission Class Rating

Since TL is frequency dependent, it is generally reported in the one-third octave frequency bands between 125 and 4000 Hz. As a convenience, a single-number rating method has been developed that allows a single value to be ascribed to a transmission loss spectrum that is a set of 16 one-third octave band TL values. This rating is referred to as the sound transmission class (STC), which has been defined in ASTM E413.²⁵ This standard defines a procedure for determining the STC rating for a TL spectrum that involves fitting a specified contour to one-third octave band TL data.

The STC value was originally developed to approximate the performance of a material in reducing the transmission of intelligible speech sounds and other household sounds. The STC characterization of TL is useful for a quick comparison of materials, but it is not necessarily useful for assessing the performance of a material with respect to other nonspeech sounds such as music and transportation noise sources. For this purpose, it is necessary to consider octave or third octave band TL spectra with specific attention paid to sound in the low-frequency range, typically at frequencies below 500 Hz. The STC contour is shown in Fig. 5. Determining the STC for a partition construction and/or material involves fitting this contour

Figure 5 A $\frac{1}{4}$ -in. glass sound transmission loss and STC contour. (1 in. = 2.54×10^{-2} m.)

to the 16 one-third octave band TL values. This procedure involves raising or lowering the contour until the following two rules are met:

1. The contour may not be raised above the point at which the TL in any one-third octave band falls more than 8 dB below the contour.
2. The contour may not be raised above the point at which the total number of deficiencies is greater than 32.

A deficiency occurs when the TL data in any one-third octave band falls below the contour. For example, three deficiencies would be when the TL data in any one-third octave fall 3 dB below the contour, or when the data in three one-third octave bands fall 1 dB below the contour. Figure 5 further illustrates the meaning of a deficiency.

The STC rating from the contour fitting procedure is the TL value of the contour at 500 Hz. This is illustrated in Figs. 5 and 6.

In Fig. 5, $\frac{1}{4}$ -in. monolithic glass is shown to have an STC rating of 31. In this example, the STC contour placement is constrained by the maximum allowed 8 dB deficiency at 2500 Hz (rule 1).

In Fig. 6, which shows TL data for $\frac{1}{4}$ -in. laminated glass, the dip in the TL data, characteristic of $\frac{1}{4}$ -in. monolithic glass, is removed by the damping interlayer. In the case of $\frac{1}{4}$ -in. laminated glass, the STC contour placement is constrained by the maximum 32-dB deficiency requirement (rule 2).

4.6 Field Sound Transmission Class Rating

The field sound transmission class (FSTC) rating is used for in situ wall and floor/ceiling sound isolation

Figure 6 A $\frac{1}{4}$ -in. laminated glass sound transmission loss and STC contour. (1 in. = 2.54×10^{-2} m.)

performance assessment.²⁶ The standard requires the measurement of sound transmission loss and includes a required procedure to show that the FSTC rating was not influenced by flanking of sound around the partition intended to be tested. Sound transmission class and FSTC ratings are intended by standard to be equivalent; however, practical experience indicates that FSTC ratings tend to be up to five rating points less than laboratory-measured STC ratings.

4.7 Noise Isolation Class

The NIC rating is similar to the STC and FSTC. It differs in that the standard STC rating contour is applied to the one-third octave band noise reduction data measured in a field situation, rather than the transmission losses measured in the field.²⁴ No correction to the measured noise reduction data is made to account for partition size, receiving room absorption, or sound flanking. Like the STC and FSTC ratings, the field-measured NIC rating of a noise reduction spectrum is equal to the value of the contour crossing at 500 Hz. In the absence of sound flanking, the NIC is generally within five points of the laboratory STC rating for typical building partition constructions. The NIC rating is used to assess the sound isolation performance of in situ partition constructions, especially complicated ones that involve multiple sound transmission paths that are not suited for laboratory testing. There are no widely used standards using the NIC rating; however, the NIC rating is often used in lieu of STC and FSTC ratings.

4.8 Normalized Noise Isolation Class

The normalized noise isolation class (NNIC) is the same as the NIC rating except the receiving room absorption is normalized to correspond to a 0.5-s reverberation time.²⁴

4.9 Outdoor-Indoor Transmission Class

The STC rating was developed to assess the sound isolation performance of partitions and materials with respect to speech and household sounds, that is, sounds produced by home appliances and entertainment equipment.²⁷ “Household sound” tends to be rich in mid- and high-frequency sound energy. However, environmental sound, typically associated with transportation systems and equipment, is rich in low- and mid-frequency sound energy. The outdoor-indoor transmission class (OITC) rating is a single-number rating that can be used for comparing the sound isolation performance of building facades and facade elements. The rating has been devised to quantify the ability of these to reduce the perceived loudness of ground and air transportation noise transmitted into buildings. This standard is contained in ASTM E1332-90 (R2003) Standard Classification for Determination of Outdoor-Indoor Transmission Class.²⁸

The standard establishes a single-number rating, the OITC, by defining a standard spectrum of ground and air transportation noise. This spectrum is used with sound transmission loss data measured in a laboratory using the ASTM E90 method and a mathematical relationship given in the standard to calculate the OITC rating.

The OITC rating is similar to the STC rating in that it uses ASTM E90 TL data and uses these data to derive a single-number rating that increases with increasing sound isolation ability. It differs in that the OITC does not involve a contour fitting process but instead uses a standard spectrum and a mathematical relationship. The mathematical relationship is as follows:

$$\text{OITC} = 100.14 - 10 \log \sum_f 10^{(L_f - T L + A_f)/10} \text{ dB}$$

Table 8²⁹ presents a worksheet summarizing the method for calculating the OITC rating for $\frac{1}{4}$ -in. glass. As indicated in Table 8, the OITC rating for $\frac{1}{4}$ -in. glass is 29. Note that the TL in the 80-Hz band in the worksheet of Table 8 is not shown since it was not measured. The actual TL value in the 80-Hz band, were it included, would not affect the OITC rating indicated in this table.

4.10 Impact Isolation

In residential buildings, quantifying the impact isolation of floor/ceiling constructions with respect to footfall is defined in ASTM E492-04³⁰ and ASTM E1007-04³¹ for laboratory and field situations, respectively. Both standards involve placing a mechanical impacting device called a tapping machine on the floor of the construction to be tested and measuring resulting sound levels below.

The design and use of the tapping machine are described in ISO 140/6.³² The result of the test is a one-third octave band impact sound pressure level in the room beneath the floor/ceiling construction being tested.

Table 8 Worksheet for Calculating the OITC Rating of $\frac{1}{4}$ -in. Glass

Band Center Frequency (Hz) (1)	Reference Sound Spectrum (dB) (2)	A-Weighting Correction (dB) (3)	Column 2 plus Column 3 (dB) (4)	Specimen TL (dB) (5)	Column 4 minus Column 5 (dB) (6)	$10^{(\text{Column 6}/10)}$ (7)
80	103	-22.5	80.5

4.11 Impact Isolation Class

Similar to the STC, the impact isolation class (IIC)³³ rating is a single-number rating that facilitates the comparison of the impact sound isolation performance of floor/ceiling constructions. The IIC rating is determined by fitting a standard contour to the one-third octave band sound pressure level data measured in accordance with ASTM E 492.

4.12 Field Impact Isolation Class

The field impact isolation class (FIIC) rating is the same as the IIC rating except it is used to rate the impact sound insulation performance of in situ floor/ceiling constructions and is used in conjunction with the ASTM E 1007³¹ test method. The standard includes procedures for assessing flanking conditions.

5 DESCRIPTORS ASSESSING THE QUALITY OF SOUND INSIDE BUILDING SPACES

5.1 Reverberation Time

The reverberation time (T_{60}) is the time it takes for sound to decay by 60 dB. Reverberation time is controlled in interior building spaces to enhance speech intelligibility or enhance music quality. Generally, speech intelligibility benefits from a short reverberation time (typically 1 s) while orchestral concert and organ music benefit from long reverberation times (2 to 5 s). Figure 7 presents criteria for reverberation time in spaces according to use for music or speech and according to room volume.

There are four generally accepted methods for calculating the reverberation time. The first and probably most widely used is the *Sabine equation*. It is more appropriately used in moderately to highly reverberant spaces. The Sabine equation is as follows:

$$T_{60} = \frac{0.049V}{A} \quad (\text{English units})$$

The second method for determining room reverberation is the *Norris-Eyring equation*. It is most appropriately used in highly absorptive and large rooms. The Norris-Eyring equation is as follows:

$$T_{60} = \frac{0.049V}{(-S) \ln(1 - \alpha)} \quad (\text{English units})$$

The third method for determining room reverberation is the *Fitzroy equation*. It is used primarily for rooms where the absorption of parallel surfaces is approximately the same. The Fitzroy equation is as follows:

$$T_{60} = \frac{X}{S} \left(\frac{0.049V}{S \bar{\alpha}_x} \right) + \frac{Y}{S} \left(\frac{0.049V}{S \bar{\alpha}_x} \right) + \frac{Z}{S} \left(\frac{0.049V}{S \bar{\alpha}_x} \right) \quad (\text{English units})$$

Figure 7 Typical impact sound pressure level spectrum and IIC contour.

In the above equations, V is room volume, S is room surface area, A is room absorption, $\bar{\alpha}$ is average sound absorption coefficient (the x , y , and z subscripts are the average sound absorption coefficients of walls normal to the x , y , and z axes), and X , Y , and Z are the surface areas of walls normal to the x , y , and z axes. If units of volume, surface area, and absorption are metric, then the 0.049 constant in each equation should be 0.161.²⁸

5.2 Room Constant

Room constant (R) is defined as the ratio of room sound absorption to the quantity 1 minus the average room absorption coefficient. Using the above symbol definitions, the relationship is expressed as

$$R = \frac{A}{1 - \bar{\alpha}}$$

There are no criteria that make use of room constant; however, it can be useful in assessing the *critical distance*, defined as the distance from a source at which the reverberant field sound pressure level equals the directly radiated sound pressure level.

5.3 Articulation Index

The articulation index (AI) is a weighted proportion of a speech signal usable to convey information. The procedure³⁵ for estimating articulation index involves accounting for signal strength, background or masking noise, time-varying character of background noise, speech signal clipping, and reverberation. The estimation procedure is carried out in one-third or full octave frequency bands. The calculated articulation index is used to estimate percent of syllables, words, or sentences

understood correctly. This analysis can be used to assess both speech intelligibility or its inverse, speech privacy. AI is also described in Section 6 of Chapter 34.

5.4 Speech Transmission Index

The speech transmission index (STI) is similar to the articulation index. It differs in that the STI uses a modulation transfer function.^{36,37} In its evaluation, it incorporates a procedure for expressing the loss in articulation produced by room reverberation as an equivalent background noise contribution, which can be added to the actual measured background noise level.³⁸

5.5 Rapid Speech Transmission Index

The rapid speech transmission index (RaSTI) is similar to the STI, uses fewer modulation frequencies, and incorporates only speech and background sound levels in only two octave bands—500 and 2000 Hz. The RaSTI value is considered sufficiently accurate only if no nonlinearities in speech transmission exist and if the background sound pressure level is devoid of strong tonal components.

CHAPTER 107

ISO RATINGS AND DESCRIPTORS FOR THE BUILT ACOUSTICAL ENVIRONMENT

Heinrich A. Metzen
DataKustik
Greifenberg, Germany

1 INTRODUCTION

In 1988, the European Building Products Directive moved to harmonize technical standards and guidelines, thus enabling the free trade of building materials and products throughout the member states of the European Community.¹ Protection against noise is one of the so-called essential requirements applying to construction works (both building and civil engineering works). Others are mechanical resistance and stability, safety in case of fire, energy economy and heat retention, safety in use, and hygienic, health, and environmental aspects. As far as sound insulation is concerned, the task was to draft new or to revise existing standards to cover all relevant technical aspects dealing with measurement, weighting, and calculation procedures for building products, elements, and buildings. Due to the Vienna Agreement in 1991 between the European Standardization Body (CEN) and the International Organization for Standardization (ISO), this huge task was heavily facilitated as existing ISO standards were allowed to be revised under CEN or ISO with a final parallel voting procedure. This concerned mainly the revision of the ISO 140- and ISO 717- series covering the measurement of sound insulation of building elements and of buildings and the procedures for weighting of spectral data resulting in single-number ratings. Furthermore, the sound-absorbing properties of building products are tested according to ISO 354 while a weighting procedure for specifying sound absorption by a single-number rating did not exist. Further acoustical properties related to building products that had to be covered are noise from water and wastewater supply systems, dynamic stiffness and airflow resistivity of acoustic materials, and survey test methods for airborne and impact sound insulation, besides the standard test methods in ISO 140.

2 AIRBORNE SOUND INSULATION

The revision of ISO 717-1 (1982 edition) originated from discussions in ISO about the suitability of the reference curve method for specifying performance with respect to outdoor noise. An ISO study group was set up that analyzed and listed the main points of criticism:

- The single-number ratings obtained by applying the ISO reference curve (e.g., the weighted sound reduction index R_w *) are not sufficiently sensitive

to low frequencies, while the high frequencies cause a strong impact on the final result.

- The reference curve method is not suitable to express element or building performance for different noise spectra, such as road noise traffic with dominating low frequencies.
- This combines with the request to extend the frequency range by the third octaves 50 to 80 Hz and 4000 to 5000 Hz.
- Several European countries established national rules that qualification tests on site can or have to be performed in octave band widths. The new rating methods, therefore, had to include procedures for data in third octaves and in octaves.

Furthermore, the so-called 8-dB rule was a point of discussion. The first edition of ISO/R 717 (1968) stated that the average of unfavorable deviations should be not more than 2 dB, and that any one-third octave band value should be not more than 8 dB below the shifted reference curve. In ISO 717-1 (1982 edition) deviations of more than 8 dB had just to be stated without influencing the final rating.

The new edition (1996) of ISO 717-1² describes the procedures to calculate single-number ratings from measurement results in frequency bands of building elements and of buildings considering the former discussions. This includes:

- Single-number quantities for airborne sound insulation between rooms in buildings and of building elements, such as walls, floors, windows, and doors.
- Spectrum adaptation terms C and C_{tr} to correct the single-number ratings with respect to two different sound pressure level spectra, referring to an indoor (term C) and a traffic noise spectrum (term C_{tr}).
- Procedures to evaluate single-number ratings for measurement results in third octave (laboratory and field tests) and in octave bands (field tests only) in accordance with the ISO 140 series.

The single-number quantities obtained by the reference method can be combined with one of the spectrum adaptation terms as a sum to characterize the sound

*Subscripts in this chapter have the following meanings: c = ceiling, e = element, f = flanking, n = normalized, s =

surface, T = reverberation time, w = weighted, and $2m = 2$ metres.

Table 1 Application of Single-Number Quantities for Airborne Sound Insulation in Conjunction with Spectrum Adaptation Terms (Examples)

Objective	Examples
Specifying element performance	$R_w(C; C_{tr}) = 50 (-2; -7)$ dB $D_{n,f,w}(C; C_{tr}) = 45 (-1; -5)$ dB
Specifying building performance	$R'_w(C; C_{tr}) = 52 (-1; -6)$ dB or $D_{n,w}(C; C_{tr}) = 50 (-2; -5)$ dB or $D_{nT,w}(C; C_{tr}) = 53 (-1; -5)$ dB
Stating the minimum requirement between rooms (e.g., in building regulations)	$R_w \geq 53$ dB or $R'_w + C_{50-3150} \geq 53$ dB or $D_{nT,w} + C_{tr} \geq 45$ dB

insulating properties of building elements or the acoustical performance of buildings between rooms inside buildings or from the outside to the inside (Table 1).

The advantage of this solution is that the former reference method could be kept and test results applying

former editions of ISO 717-1 match still with the principal weighting procedure. On the other hand, the spectrum adaptation terms can be calculated from the measured spectrum without requiring a new test. As the spectrum adaptation terms are sensitive to deviations in single-frequency bands, the former 8-dB rule no longer applies. Meanwhile, several European countries have installed revised or new national building regulations making use of the new weighting procedures (Table 2). In several European countries additional national standards specifying classification schemes for increased sound insulation exist.³

The 1996 edition of ISO 717-1 has created a large diversity of descriptors used in the ISO member countries. As spectrum adaptation terms can be calculated also for the enlarged frequency range (downward to 50 Hz and/or upward to 5000 Hz), a maximum of eight spectrum adaptation terms result from one spectrum, for example, for the weighted sound reduction index R_w :

$$\begin{aligned}
 &R_w(C; C_{tr}; C_{100-5000}; C_{tr,100-5000}; C_{50-5000}; \\
 &C_{tr,50-5000}; C_{50-3150}; C_{tr,50-3150}) \\
 &= 50(-2; -7; -1; -7; -2; -8; -3; -8) \text{ dB}
 \end{aligned}$$

Legal requirements for sound insulation against outdoor noise differ even more than requirements for sound insulation inside buildings. In some countries

Table 2 Airborne Sound Insulation Requirements in European Countries (as of 2004)^a

Country	Descriptor	Multistorey Buildings (dB)	Semidetached and Row Houses (dB)
Austria	$D_{nT,w}$	≥ 55	≥ 60
Belgium ^b	$D_{nT,w}$	≥ 54	≥ 58
Czech Republic	R'_w	≥ 52	≥ 57
Denmark	R'_w	$\geq 52^c$	≥ 55
Estonia	R'_w	≥ 55	≥ 55
Finland	R'_w	≥ 55	≥ 55
France	$D_{nT,w} + C$	≥ 53	≥ 53
Germany	R'_w	$\geq 53^c$	≥ 57
Hungary	R'_w	≥ 52	≥ 57
Iceland	$R'_w{}^c$	≥ 52	≥ 55
Latvia	R'_w	≥ 54	≥ 54
Lithuania	$D_{nT,w}$ or R'_w	≥ 55	≥ 55
Italy	R'_w	≥ 50	≥ 50
Netherlands	$I_{lu,k} (R'_w \approx 55 + I_{lu,k})$	≥ 0	≥ 0
Norway	R'_w	$\geq 55^d$	$\geq 55^d$
Poland	$R'_w + C$	$\geq 50^c$	≥ 52
Portugal	$D_{n,w}$	≥ 50	≥ 50
Russia	I_b	≥ 50	^e
Slovakia	R'_w	≥ 52	≥ 52
Slovenia	R'_w	≥ 52	≥ 52
Spain ^b	$D_{nT,w} + C_{100-5000}$	≥ 50	≥ 50
Sweden	$R'_w + C_{50-3150}$	≥ 53	≥ 53
Switzerland	$D_{nT,w} + C$	≥ 54	≥ 54
United Kingdom	$D_{nT,w} + C_{tr}$	≥ 45	≥ 45

^aSee also Table 4 in Chapter 114.

^bProposed new requirements.

^cFor vertical direction the requirement is 1 dB higher.

^dIt is recommended that the same criteria are fulfilled by $R'_w + C_{50-3150}$.

^eNo requirements.

Table 3 Single-Number Quantities of Airborne Sound Insulation of Building Elements

Derived from One-Third Octave Band Values			
Single-Number Quantity	Term and Symbol	Defined in	Equation ^a
Weighted sound reduction index R_w	Sound reduction index R	ISO 140-3	$R = L_1 - L_2 + 10 \log \frac{S}{A}$
Weighted suspended-ceiling normalized level difference $D_{n,c,w}$	Suspended-ceiling normalized level difference $D_{n,c}$	ISO 140-9	$D_{n,c} = L_1 - L_2 + 10 \log \frac{A_0}{A}$
Weighted element-normalized level difference $D_{n,e,w}$	Element-normalized level difference $D_{n,e}$	ISO 140-10	$D_{n,e} = L_1 - L_2 + 10 \log \frac{A_0}{A}$
Weighted normalized flanking level difference $D_{n,f,w}$	Normalized flanking level difference $D_{n,f}$	ISO 10848-2	$D_{n,f} = L_1 - L_2 + 10 \log \frac{A_0}{A}$

^a L_1 = average sound pressure level in the sending room, in dB

L_2 = average sound pressure level in the receiving room, in dB

S = area of the test specimen, in square metres (equals the test opening)

A = equivalent sound absorption area in the receiving room, in square metres

A_0 = reference absorption area ($A_0 = 10 \text{ m}^2$)

the required sound insulation of facades is specified as a function of the outdoor noise level, perhaps with different day and night requirements. In a number of countries the indoor level $L_{A,eq,24h}$ must meet a predefined limit. In some countries there are no general or national requirements but only local or district requirements. In addition, the methods for determination of the exterior noise exposure vary considerably. In total, the situation is even more complex than with indoor noise. In the mean time, the Technical Committee Room and Building Acoustics (TC-RBA) of the European Acoustical Association (EAA) has initiated a project to gather information on classification schemes and to give guidance on how to harmonize the use of concepts for sound insulation.

2.1 Descriptors for Element Performance and for Building Performance

The single-number ratings specifying element and building performance and the measured term according to the ISO 140 series and other measurement standards are listed in Tables 3 and 4. All element data is measured in test facilities with suppressed flanking transmission.

2.2 Weighting Procedure

The ISO weighting procedure applies to measurement results obtained in accordance with ISO 140-3, ISO 140-4, ISO 140-5, ISO 140-9, ISO 140-10, and ISO 10848-2 in the following frequency ranges:

- From 100 to 3150 Hz for one-third octave bands
- From 125 to 2000 Hz for octave bands (for field tests only)

The spectral data shall be given to an accuracy of 0.1 dB. The single-number rating in decibels is obtained by shifting the relevant reference curve in steps of 1 dB toward the measured curve until the sum of unfavorable deviations is as large as possible but not more than 32.0 dB (measurement in 16 one-third octave bands) or 10.0 dB (measurement in 5 octave bands). An unfavorable deviation at a particular frequency occurs when the result of measurements is less than the reference value. Only the unfavorable deviations are taken into account. The value of the reference curve at 500 Hz after having shifted the reference curve is the single-number rating R_w , R'_w , $D_{n,w}$ or $D_{nT,w}$ (see Tables 3 and 4). The reference curve in octave bands should be applied just with results of measurements in octave bands in the field (Fig. 1).

By the slightly different shape of the two reference curves, it is ensured that the difference among single-number ratings calculated from field measurements in third octave or in octave bands is ± 1 dB at the most.

2.3 Spectrum Adaptation Terms

The specification of the spectrum adaptation terms C and C_{tr} is a normative requirement when stating the performance of building elements or of buildings according to ISO 717-1.² The spectrum adaptation terms for the enlarged frequency range $C_{100-5000}$; $C_{tr,100-5000}$; $C_{50-5000}$; $C_{tr,50-5000}$; $C_{50-3150}$; and $C_{tr,50-3150}$ may be given if available.

The spectrum adaptation term is a figure in decibels that has to be added to an ISO single-number rating (e.g., R_w or $D_{nT,w}$) to express element or building performance with respect to a sound pressure level spectrum. As the spectrum adaptation terms are sensitive to negative deviations in single bands from the

Table 4 Single-Number Quantities of Airborne Sound Insulation in Buildings

Derived from One-Third Octave or Octave Band Values			
Single-Number Quantity	Term and Symbol	Defined in	Equation ^a
Weighted apparent sound reduction index R'_w	Apparent sound reduction index R'	ISO 140-4	$R' = L_1 - L_2 + 10 \log \frac{S}{A}$
Weighted apparent sound reduction index $R'_{45^\circ, w}$	Apparent sound reduction index R'_{45°	ISO 140-5	$R'_{45^\circ} = L_{1,s} - L_2 + 10 \log \frac{S}{A} - 1.5 \text{ dB}$
Weighted apparent sound reduction index $R'_{tr, s, w}$	Apparent sound reduction index $R'_{tr, s}$	ISO 140-5	$R'_{tr, s} = L_{eq, 1, s} - L_{eq, 2} + 10 \log \frac{S}{A} - 3 \text{ dB}$
Weighted normalized level difference $D_{n, w}$	Normalized level difference D_n	ISO 140-4	$D_n = L_1 - L_2 - 10 \log \frac{A}{A_0}$
Weighted standardized level difference $D_{nT, w}$	Standardized level difference D_{nT}	ISO 140-4	$D_{nT} = L_1 - L_2 + 10 \log \frac{T}{T_0}$
Weighted standardized level difference, $D_{ls, 2m, nT, w}$ or $D_{tr, 2m, nT, w}$	Standardized level difference $D_{ls, 2m, nT}$ or $D_{tr, 2m, nT}$	ISO 140-5	$D_{2m, nT} = L_{1, 2m} - L_2 + 10 \log \frac{T}{T_0}$

- ^a L_1 = average sound pressure level in the sending room, in dB
 L_2 = average sound pressure level in the receiving room, in dB
 $L_{1,s}$ = average sound pressure level on the surface of the test specimen, in dB
 $L_{1,2m}$ = outdoor sound pressure level 2 m in front of the facade, in dB
 $L_{eq, 1, s}$ = average value of the equivalent continuous sound pressure level on the surface of the test specimen including reflecting effects from the test specimen and facade, in dB
 $L_{eq, 2}$ = average value of the equivalent continuous sound pressure level in the receiving room, in dB
 S = area of the test specimen, in square metres (equals the test opening)
 A = equivalent sound absorption area in the receiving room, in square metres
 A_0 = reference absorption area ($A_0 = 10^2$)
 T = reverberation time in the receiving room, in s
 T_0 = reference reverberation time ($T_0 = 0.5$ s)

**Figure 1** Reference curves for airborne sound, in one-third octave and octave bands.**Figure 2** Sound pressure level spectra L_{f1} for spectrum adaptation term C (in one-third octave and octave bands).

shifted reference curve, they replace the former 8-dB rule. In ISO 717-1 two kinds of spectrum adaptation terms (in third octave and octave bands) referring to two sound pressure level spectra are introduced.

The spectrum adaptation term C is calculated from an A-weighted pink noise spectrum (Fig. 2) and the spectrum adaptation term C_{tr} from an A-weighted urban traffic noise spectrum (Fig. 3). The spectrum adaptation terms are defined as the difference between the calculated value X_{Aj} and the single-number rating

Figure 3 Sound pressure level spectra L_{12} for spectrum adaptation term C_{tr} (in third octave and octave bands).

X_w resulting from the reference curve procedure:

$$C_j = X_{Aj} - X_w \quad (\text{in dB})$$

with C_j = spectrum adaptation term for spectrum j , where

$j = 1$, A-weighted pink noise

$j = 2$, A-weighted urban traffic noise

X_w = single-number rating from the reference curve procedure

X_{Aj} = calculated value according to

$$X_{Aj} = -10 \log \sum 10^{(L_{ij}-X_i)/10} \quad (\text{in dB})$$

i = index for third octaves 100 to 3150 Hz
resp., octaves 125 to 2000 Hz

L_{ij} = sound pressure levels at frequency i for the spectrum j

X_i = measured value in frequency band i (R_i , R'_i , $D_{n,i}$, $D_{nT,i}$), given to the nearest 0.1 dB

The spectra L_{i1} for A-weighted pink noise and L_{i2} for A-weighted urban traffic noise are normalized to an energy sum of 0 dB. The spectrum adaptation terms are calculated to 0.1 dB and rounded according to ISO 31-0.⁴

Table 5 shows a scheme for the calculation of the single-number rating according to the ISO-reference curve and the spectrum adaptation terms C and C_{tr} for the normative frequency range of 100 to 3150 Hz. The statement of result in this case is

$$R_w(C; C_{tr}) = 50(-1; -5) \text{ dB}$$

Both spectrum adaptation terms may be applied to additional types of noise. Table 6 lists a number of different noise sources to which the spectrum adaptation terms, C or C_{tr} , can be attached. If the A-weighted spectrum of a certain type of noise is known, it can be compared with the data in Figs. 2 and 3 to decide which spectrum adaptation term may apply to the present spectrum.

Table 6 Relevant Spectrum Adaptation Term for Different Types of Noise Source

Type of Noise Source	Relevant Spectrum Adaptation Term
Living activities (talking, music, radio, TV)	C (spectrum No.1)
Children playing	
Railway traffic at medium and high speed	
Highway road traffic >80 km/h	
Jet aircraft, short distance	
Factories emitting mainly medium- and high-frequency noise	C_{tr} (spectrum No.2)
Urban road traffic	
Railway traffic at low speeds	
Aircraft, propeller driven	
Jet aircraft, large distance	
Disco music	
Factories emitting mainly low- and medium-frequency noise	

Additional procedures for the calculation of spectrum adaptation terms (based on different spectra L_{i1} and L_{i2}) for the enlarged frequency range (50 to 3150 Hz, 100 to 5000 Hz, or 50 to 5000 Hz) are contained in an additional, informative annex of ISO 717-1.

2.4 Examples

From studies on a number of constructions, the following conclusions can be drawn:

- For monolithic walls and floors with increasing sound reduction index over frequency, the spectrum adaptation term C is in the range of -1 to -2 dB (Table 7). The value of C is governed by the low- and medium-frequency range. The spectrum adaptation term C_{tr} for monolithic exterior walls is about $C_{tr} = -4$ dB. As the levels of spectrum L_{i2} at the low frequencies are higher than with spectrum L_{i1} , the term C_{tr} is much more dominated by the difference $L_{i2} - R_i$ in the first third octaves.
- Double walls (such as heavy walls with wall linings or lightweight walls with metal or wooden studs) show spectrum adaptation terms C in the range of -2 to -5 dB. This is caused by the double-wall resonance frequency at low frequencies and—for lightweight elements—by the reduced insulation near the critical frequency in the high-frequency region. The spectrum adaptation term C_{tr} for double-wall constructions with resonance frequencies $100 \text{ Hz} \leq f_0 \leq 160 \text{ Hz}$ can drop down to $-8 \text{ dB} \leq C_{tr} \leq -12 \text{ dB}$ while for lower resonance frequencies ($f_0 \leq 80 \text{ Hz}$) C_{tr} tends to be more positive with a range of $-6 \text{ dB} \leq C_{tr} \leq -8 \text{ dB}$.
- Glazing constructions with air or argon as fill gases have a spectrum adaptation term C of -1 to -2 dB and a spectrum adaptation term C_{tr}

of -3 dB to -7 dB (depending on gap width and thickness of panes).

3 IMPACT SOUND INSULATION

The ISO procedures for obtaining the single-number ratings for impact sound insulation have been thoroughly discussed in the revision of the former ISO 717-2 (1982 edition). The main points of criticism were:

- The shape of the ISO reference curve lacks the necessary influence on low-frequency impact noise while the high frequencies have too strong an influence on the final single-number rating.
- The single-number rating (weighted normalized impact sound pressure level) does not reflect the subjective disturbance of impact noise such as walking.
- The weighting procedure causes the subjective impact noise disturbance of heavy floors to be underrated, while lightweight timber floors with wooden joists without additional carpets or floating floors are overrated.

These problems are caused by the spectral characteristics of the impact noise source. The force spectrum of the standardized tapping machine is dominated by higher frequencies, which is not comparable with real impact noise sources (e.g., walking, moving of chairs/tables, children playing, etc.). Several new reference curves with different shapes have been discussed and assessed. Finally, it was decided keep the existing reference curve procedure to avoid confusion among users and to prevent malpractice, which possibly would occur with several single-number ratings characterizing the impact sound insulation of floors.

The new edition of ISO 717-2⁵ describes the procedures to calculate single-number ratings from measurement results in frequency bands of building elements and of buildings. This includes:

- Single-number quantities for the impact sound insulation in buildings and of floors (ISO 140-6 and ISO 140-7).
- Single-number quantities for the impact sound reduction of carpets and floating floors from the results of measurements carried out in accordance with ISO 140-8.
- Procedures to evaluate single-number ratings for measurement results in third-octave (laboratory and field tests, ISO 140-6 and ISO 140-7) and in octave bands (field tests only, ISO 140-7).

With this approach, the single-number quantities obtained by the reference method (e.g., the weighted normalized impact sound pressure $L_{n,w}$) is maintained as the prime rating quantity.

An informative annex introduces a spectrum adaptation term for impact noise by a walking person (C_i , $i = \text{impact}$). Several studies have shown that the unweighted (linear) impact level generated by the tapping machine is more representative of the A-weighted walking noise levels for all types of floor.⁶⁻⁹

Table 7 Weighted Sound Reduction Index R_w and Spectrum Adaptation Terms C and C_{tr} of Typical Building Elements (Examples)

No.	Element Type	Layer Description	R_w (C ; C_{tr})
1	Monolithic wall	Aerated concrete 100 mm, plastered	39 (−1; −4) dB
2	Monolithic floor	Concrete 200 mm	58 (−1; −5) dB
3	Monolithic wall with wall lining	Aerated concrete 100 mm, plastered Mineral wool slab 50 mm (glued) Render 15 mm	51 (−2; −8) dB
4	Monolithic floor with floating floor	Concrete 160 mm Glass wool slab 13 mm Calcium-sulfate screed 40 mm	64 (−4; −11) dB
5	Timber floor with wooden joists (cross section 120 × 180 mm)	Wooden particle board 22 mm Mineral wool 27 mm Wooden particle board 22 mm Glass wool 100 mm (inside cavity) Gypsum board 12.5 mm (on wooden battens)	64 (−4; −11) dB
6	Lightweight double-wall (single metal studs 60 × 100 mm)	Gypsum board 12.5 mm Glass wool 100 mm (inside cavity) Gypsum board 12.5 mm	52 (−2; −7) dB
7	Lightweight double-wall (single wooden studs 38 × 89 mm)	Gypsum board 13 mm (on resilient furring channel) Glass wool 90 mm (inside cavity) Gypsum board 13 mm	48 (−5; −13) dB
8	Inclined roof (with wooden rafters)	Concrete tiles Glass wool 160 mm (between rafters) Gypsum board 12.5 mm (on wooden battens)	52 (−3; −9) dB
9	Metal facade	Corrugated metal sheet 0.88 mm Glass wool 100 mm Corrugated metal sheet 0.88 mm	36 (−2; −7) dB
10	Glazing	4-mm glass 12-mm air 6-mm glass	34 (−1; −4) dB
11	Window	Aluminum frame with center sealing at frame and interior rabbet sealing Glazing: 6-mm glass, 16-mm air, 4-mm glass	39 (−3; −6) dB

The intention of this spectrum adaptation term is to allow—in combination with the single-number rating according to the reference curve—a more correct weighting with respect to the excitation by walking persons. This rating is also more restrictive to single noise peaks and replaces thereby the 8-dB rule used in the former (1982) edition of ISO 717-2. Studies clearly indicate that the difference between the ISO single-number rating plus the spectrum adaptation term for impact noise ($L_{n,w} + C_i$) and the A-weighted impact noise by a walking person L_A on several types of floors is more or less constant, at least for hard footwear.¹⁰

The single-number quantities are intended for rating the impact sound insulation of floors, bare floors, and of carpets or floor coverings and for the formulation of acoustical requirements in building codes. The specification of numerical values of the single-number quantities remains a national task (Table 8).

As for airborne sound insulation, several European countries have meanwhile revised their national building

regulations (Table 9). Furthermore, national classification schemes for increased sound insulation make use of the spectrum adaptation term for walking noise.³

3.1 Descriptors for Element Performance and for Building Performance

The single-number ratings specifying element and building performance with respect to impact sound insulation properties and the measured term according to the ISO 140 series and other measurement standards are listed in Tables 10 and 11. As with airborne sound insulation, all element data is measured in test facilities with suppressed flanking transmission.

3.2 Weighting Procedures

The ISO weighting procedure applies to measurement results made in accordance with ISO 140-6, -7 and ISO 10848-2 in the frequency ranges:

- From 100 Hz to 3150 Hz for one-third-octave bands

Table 8 Application of Single-Number Quantities for Impact Sound Insulation in Conjunction with the Spectrum Adaptation Term for Walking Noise (Examples)

Objective	Examples
Specifying element performance (floor)	$L_{n,w} = 52$ dB $L_{n,w} (C_i) = 52$ (2) dB
Specifying element performance (carpet or floating floor)	$\Delta L_w = 34$ dB $\Delta L_w (C_{i,\Delta}) = 34$ (−13) dB $\Delta L_{lin} = \Delta L_w + C_{i,\Delta} = 21$ dB
Specifying building performance	$L'_{n,w} = 53$ dB $L'_{nT,w} = 50$ dB
Stating the minimum requirement between rooms (e.g., in building regulations)	$L'_{n,w} \leq 53$ dB or $L'_{nT,w} \leq 53$ dB or $L'_{n,w} + C_i \leq 53$ dB $L'_{n,w} + C_{i,50-2500} \leq 56$ dB

- From 125 Hz to 2000 Hz for octave bands (for field tests only)

The spectral data shall be given to 0.1 dB. The single-number rating in decibels is obtained by shifting the

reference curve in steps of 1 dB toward the measured curve until the sum of unfavorable deviations is as large as possible but not more than 32.0 dB (measurement in 16 one-third octave bands) or 10.0 dB (measurement in 5 octave bands). An unfavorable deviation at a particular frequency occurs when the measurement results exceed the reference value. Only the unfavorable deviations shall be taken into account.

As with airborne sound insulation, two types of reference curve exist: one for data in one-third octave band and another for data in octave band width (Fig. 4). For the evaluation of data in one-third octave bandwidth, the single-number rating equals the value in decibels of the reference curve at 500 Hz, after having shifted the reference curve. Due to the different bandwidth, the single-number rating for the evaluation of data in octave band is the value in decibels of the reference curve at 500 Hz, after having shifted the reference curve, reduced by 5 dB.

The reference values for the octave bands are equivalent to the energetic sum of the reference values in one-third octave bands. The reference value for the octave band of 2000 Hz has been reduced to take care of the one-third octave band of 3150 Hz, which (for bare massive floors) may contribute considerably to the

Table 9 Impact Sound Insulation Requirements in European Countries (as of 2004)^a, see also Table 5 in Chapter 114)

Country	Descriptor	Multistorey Buildings (dB)	Semidetached and Row Houses (dB)
Austria	$L'_{nT,w}$	≤ 48	≤ 46

T = reverberation time in the receiving room, in seconds

T_0 = reference reverberation time ($T_0 = 0.5$ s)

**Figure 4** Reference curves for impact sound, in one-third octave and in octave bands.

unfavorable deviations. This ensures that deviations between single-number ratings obtained from data in one-third octave or in octave bands differ ± 1 dB at the most.

The weighting procedure for the improvement of impact sound insulation by carpets or floatings floors is described by the reduction in impact sound pressure level ΔL , measured in one-third octave bands on a heavy concrete floor of (140 ± 20) mm thickness. The frequency-dependent reduction in impact sound pressure level ΔL when tested on homogeneous concrete floors is independent of the normalized impact sound pressure level of the bare concrete floor $L_{n,0}$. However, as the weighted normalized impact sound pressure level of the floor with and without a floor covering depends to some extent on $L_{n,0}$ a reference curve is required to obtain the same weighted reduction of impact sound pressure level ΔL_w for the same floor covering on different types of bare floors being installed in laboratories. The weighted normalized impact sound pressure level $L_{n,r,0,w}$ of the reference floor is 78 dB and represents the idealized spectrum of homogeneous concrete floor of 120 mm thickness. The weighted reduction in impact sound pressure level ΔL_w is calculated from:

$$\begin{aligned} L_{n,r} &= L_{n,r,0} - \Delta L \\ \Delta L_w &= L_{n,w,r,0} - L_{n,w,r} = 78 \text{ dB} - L_{n,w,r} \text{ in dB} \end{aligned}$$

Table 12 Normalized Impact Sound Pressure Level of the Reference Floor $L_{n,r,0}$

f (Hz)	100	125	160	200	250	315	400	500
$L_{n,r,0}$ (dB)	67	67.5	68	68.5	69	69.5	70	70.5
f (Hz)	630	800	1000	1250	1600	2000	2500	3150
$L_{n,r,0}$ (dB)	71	71.5	72	72	72	72	72	72

where $L_{n,r}$ = calculated normalized impact sound pressure level of the reference floor with the floor covering under test
 $L_{n,r,0}$ = defined normalized impact sound pressure level of the reference floor (Table 12),
 ΔL = reduction in impact sound pressure level measured in accordance with ISO 140-8
 $L_{n,w,r}$ = calculated weighted normalized impact sound pressure level of the reference floor with the floor covering under test
 $L_{n,r,0,w}$ = obtained from the spectrum $L_{n,r,0}$ by applying the reference curve method

The reduction in impact sound pressure level ΔL measured on a concrete floor slab as defined in ISO 140-8 and thus the single-number quantity L_w may only be used in conjunction with heavy floors (e.g., concrete, hollow concrete, hollow bricks). It is not appropriate for use on other types of constructions, especially with any kind of lightweight floors, such as timber floors with wooden joists.

In 1994, the ISO Working Group 22 was created to study the possibilities for setting up procedures to evaluate the improvement of impact sound insulation by carpets or floatings floors on lightweight floors, such as timber floor with wooden joists. This work resulted in the edition of ISO 140-11 specifying methods for measuring the acoustic properties of floor coverings installed on lightweight floors.¹¹ In addition, a modified tapping machine and a heavy impact source are introduced to assess the impact sound insulation of a floor covering against impact sources with strong components at low frequencies, such as human footsteps or children jumping. The procedures to obtain single-number ratings from these measurement results will be drafted by a CEN working group.

3.3 Spectrum Adaptation Term for Impact Noise

As the impact noise spectrum produced by the tapping machine does not quite represent the noise generated by walkings persons, a spectrum adaptation term for impact noise C_i is introduced in an informative annex of ISO 717-2.⁵ In combination with the single-number rating obtained by applying the reference curve method, the new value allows a more correct weighting with respect to the excitation by a walking person. The spectrum adaptation term C_i can be calculated for the normal frequency range from 100 to 2500 Hz for one-third-octave bands (from 125 to 2000 Hz for octave bands) or for the extended frequency range from 50

to 3150 Hz for one-third-octave bands (from 63 to 2000 Hz for octave bands).

As with airborne sound insulation the spectrum adaptation term for impact noise C_i represents the difference of the A-weighted energetic sum X_A for common impact noise by a walking person in buildings and the single-number rating obtained from the ISO reference curve procedure:

$$C_i = X_A - L_{n,w} \quad (\text{in dB})$$

Because the A-weighted difference between the normalized impact sound pressure level and impact noise spectra is approximately constant above frequency, the sum of the ISO single-number rating plus the spectrum adaptation term C_i can be expressed by the energetic sum $L_{n,ges}$ corrected by a constant value:

$$\begin{aligned} L_{n,w} + C_i &= 10 \log \sum 10^{(L_{n,i}-15)/10} \\ &= L_{n,ges} - 15 \text{ dB} \end{aligned}$$

The constant has been defined to result in a spectrum adaptation term for monolithic floors with floor coverings of about $C_i = 0$ dB. Thus, there exists a linear relation between the weighted normalized impact sound pressure level and the spectrum adaptation term C_i :

$$C_i = L_{n,sum} - 15 - L_{n,w} \quad (\text{in dB})$$

or

$$C_i = L'_{n,sum} - 15 - L'_{n,w} \quad (\text{in dB})$$

or

$$C_i = L'_{nT,sum} - 15 - L'_{nT,w} \quad (\text{in dB})$$

The values of $L_{n,ges}$, $L'_{n,ges}$ or $L_{nT,ges}$ are the energetic summation of the normalized, respectively, standardized impact sound pressure levels for n frequency bands, for example,

$$L_{n,sum} = 10 \log \sum_{i=1}^n 10^{L_{n,i}/10} \quad (\text{in dB})$$

The spectrum adaptation terms are calculated to 0.1 dB and rounded according to ISO 31-0.⁴

For floor coverings an additional spectrum adaptation term is required describing the improvement of impact sound insulation applying a flat (linear) weighting. This spectrum adaptation term is calculated from:

$$C_{i,\Delta} = C_{i,r,0} - C_{i,r} = -11 - C_{i,r} \quad (\text{in dB})$$

where $C_{i,\Delta}$ = spectrum adaptation term for the reduction in impact sound pressure level applying a linear weighting

$C_{i,r}$ = spectrum adaptation term for the reference floor with the floor covering under test

$C_{i,r,0}$ = spectrum adaptation term for the reference floor ($C_{i,r,0} = -11$ dB)

			$L_{n,w}$ =	77 dB			$L_{n,w}$ =	40 dB							$L_{n,w,r}$ =	41
													$\Delta L_w = L_{n,w,r,0} - L_{n,w,r} = 78$ dB	$L_{n,w,r}$ =		37
													$L_{n,r, \text{sum}} - 15$ dB	$L_{n,w,r}$ =		3.20
														C_r =		3
	$L_{n, \text{sum}} - 15$ dB	$L_{n,w}$ =	-10.7		$L_{n, \text{sum}} - 15$ dB	$L_{n,w}$ =	-2.90							-11 - C_r =		-14.2
		C_i =	-11 dB			C_i =	-3 dB							C_i, Δ =		-4 dB

The single-number rating based on the unweighted reduction in impact sound pressure level is also denoted by ΔL_{lin} :

$$\Delta L_{\text{lin}} = \Delta L_w + C_{i,\Delta}$$

Table 13 shows a scheme for the calculation of the single-number ratings according to the ISO reference curve and the spectrum adaptation terms C_i and $C_{i,\Delta}$ for the normative frequency range of 100 to 3150 Hz.

The statement of results for the bare floor and the floor with floor covering are

Bare floor: $L_{n,w}(C_i) = 77(-11)$ dB

Floor with floor covering : $L_{n,w}(C_i) = 40(-3)$ dB

A weighted normalized impact sound pressure level plus the spectrum adaptation term for flat weighting $L_{n,w} + C_i$ of 66 dB means that the bare floor is performing 11 dB better (lower impact sound pressure level) with excitation by a walking person than by the tapping machine. Thus, for bare monolithic floors the tapping machine causes a too pessimistic weighting result compared with real walking persons.

For the floor covering the result is

$$\Delta L_w(C_{i,\Lambda}) = 37(-14) \text{ dB}$$

This means that the floor covering is 14 dB less effective with respect to an excitation by a walking person in relation to the tapping machine. The tapping machine is overestimating the performance of the floor

covering when trying to assess the impact noise by walking persons.

3.4 Examples

From studies on a number of constructions the following conclusions can be drawn (Tables 14 and 15):

- Bare monolithic floors (e.g., from concrete or aerated concrete) receive a spectrum adaptation term for walking noise C_i of about -10 dB to -12 dB.
- For monolithic floors with high-performance floor coverings the spectrum adaptation term for walking noise C_i is about 0 dB.
- For lightweight floors (timber floors with wooden joists) the spectrum adaptation term C_i is slightly positive. Thus, these floors are more susceptible to walking noise than the single-number rating $L_{n,w}$ indicates.
- Floor coverings receive a spectrum adaptation term $C_{i,\Delta}$ in the range of -11 dB to -15 dB. So, floor coverings are in general less effective against impact noise by walking persons than to the excitation by the tapping machine.

4 SOUND ABSORPTION

4.1 Sound Absorption Coefficient

The method described in ISO 354 evaluates the sound absorption coefficient α_p in a reverberation chamber in one-third octaves in the frequency range from 100 to 5000 Hz.¹² The reverberation chamber shall

2	Cementitious floating floor	Calcium sulfate 40 mm Glass wool 13 mm	37 (−14) dB
3	Floor covering	PVC, 2 mm	15 (−10) dB

have a volume of at least 150 m³, while for new test rooms a minimum volume of 200 m³ is recommended. Plane absorbers as test specimen shall have a test area between 10 and 12 m² with a rectangular shape and with a ratio of width to length between 0.7 and 1. Different standard mounting conditions for plane absorbers (direct, glued, suspended, hanging, plaster materials) or for discrete sound absorbers (e.g., absorber pads or baffles) are described in a normative annex of ISO 354.

Test results for the sound absorption coefficient α_s in one-third octaves from 100 to 5000 Hz normally range from 0 to 1. However, absorption coefficients well above unity can result from the diffraction of sound at the specimen edges, which is proportional to the ratio of the perimeter and the area of the sample.¹³

4.2 Practical Absorption Coefficient

The *practical absorption coefficient* α_p according to ISO 11654¹⁴ is calculated by averaging arithmetically the sound absorption coefficients measured in third octave bands in each octave and rounding the result to the nearest 0.05 step.

$$\alpha_p = \frac{(\alpha_{i1} + \alpha_{i2} + \alpha_{i3})}{3}$$

Practical absorption coefficients $\alpha_p > 1$ are maximized to $\alpha_p = 1$.

4.3 Weighted Sound Absorption Coefficient

The single-number rating α_w is obtained from the comparison of the α_p spectrum with a reference

**Figure 5** Reference curve for sound absorption according to ISO 11654.

curve (Fig. 5). The reference curve is shifted in steps of 0.05 towards the measured value until the sum of the unfavorable deviations in the frequency range of 250–4000 Hz is less than or equal to 0.10. An unfavorable deviation occurs at a particular frequency when the measured value is less than the value of the reference curve. Only deviations in the unfavorable direction shall be counted. The weighted sound absorption α_w is defined as the value of the shifted reference curve at 500 Hz.

The reference curve is lowered to 0.8 at 250 Hz to adapt the curve to the shape of conventional porous

absorbers. The decrease at 4000 Hz is due to the fact that mechanical typewriters with strong noise emission at high frequencies are nowadays less common in office rooms and absorbers for hygienic applications show often a decreasing sound-absorbing coefficient in this frequency range, both causing the higher frequencies to be less relevant when judging noise absorption characteristics.

4.4 Shape Indicators

A shape indicator is used whenever the practical sound absorption coefficient α_p at one or more frequencies exceeds the value of the shifted reference curve by 0.25 or more. Capital letters (in parentheses) indicate in such cases that an excess occurs in the low, medium, or high-frequency domain. An excess absorption at 250 Hz is marked by the indicator *L*, an excess at 500 or 1000 Hz by *M*, and an excess at 2000 or 4000 Hz by *H*. In general, a shape indicator means that the sound absorption coefficient at one or several frequencies is considerably higher than the values of the shifted reference curve. Negative deviations (values below the reference curve) are not considered as they are already maximized to 0.1 in the curve-shifting procedure.

4.5 Examples

In Example 1 the calculation of the weighted sound absorption coefficient for a normal porous absorber with increasing sound absorption over frequency is

explained (Table 16). The reference curve is shifted in steps of 0.05 towards the measured value (i.e., downward) until the sum of the unfavorable deviations is equal or smaller 0.10. An unfavorable deviation occurs at 250 Hz and the result is $\alpha_w = 0.60$. No shape indicators are given as the differences between α_p , and the values of the shifted reference curve is less than 0.25 at all center frequencies.

In Example 2, the shape indicator is calculated for a resonance absorber (Table 17). The unfavorable deviation is equal to that of example 1 and thus the same α_w value is obtained. However, as the practical sound absorption coefficient of the absorber exceeds that of the shifted reference curve by more than 0.25 at 500 Hz, the mid-frequency (*M*) shape indicator is added resulting in the designation $\alpha_w = 0.60(M)$.

From studies on a number of practical absorber designs, the following conclusions can be drawn:

- For plane porous absorbers (e.g., mineral wool or open-cellular foams), the weighted sound absorption coefficient α_w equals quite often the measured sound absorption coefficient α at 500 Hz minus 0 to 0.10.
- The majority of plane porous absorbers receive the shape indicator *H* which means that the shifted reference curve is exceeded by more than 0.25 at 2000 or/and 4000 Hz. Hence, the absorber is more effective at these frequencies than indicated by the single-number rating α_w .

**Figure 6** Reference curves limiting the different sound absorption classes in ISO 11654.

- Resonance-type absorbers can receive various shape indicators depending on the individual characteristics of the frequency curve.
- Absorbers primarily used in office buildings at conventional wall distances receive no shape indicator when compared with the reference curve.

4.6 Sound Absorption Classes

Depending on the value of the single-number rating, α_w , absorbers can be grouped into classes (Table 18). These sound absorption classes intend to facilitate the selection of suitable absorbers for a specific applications by architects or building designers. National regulations can refer either to the weighted sound absorption coefficient or the sound absorption class.

CHAPTER 108

ACOUSTICS DESIGN IN OFFICE WORK SPACES AND OPEN-PLAN OFFICES

Carl J. Rosenberg
Acentech Incorporated
Cambridge, Massachusetts

1 INTRODUCTION

Acoustical considerations in offices relate to noise control of equipment, speech privacy, and freedom from distraction. These considerations have been shown to influence the productivity of office workers and can, therefore, have both an economic and psychological impact on the office environment. The understanding focus on office acoustics has paralleled the growth of architectural acoustics as a building science and the development of acoustical products. Tools are available for evaluating and enhancing the acoustical design of office work spaces.

Basic terms of reference have been developed for architectural acoustics in general and for analysis of office acoustics in particular. These include the A-weighted sound pressure level, sound transmission class (STC), noise criteria (NC) ratings, noise isolation class (NIC), noise reduction coefficient (NRC), and articulation index (AI; a measure of signal-to-noise ratio). These terms are used both to measure existing conditions and to predict the results of a new design. More recently, as acoustical analysis has addressed open plan office issues, newer terms and analysis tools related to speech intelligibility and privacy have been developed. Sound-masking systems have become an accepted component of acoustical design.

2 CURRENT ANALYTICAL FRAMEWORK

A seminal study by Cavanaugh et al. from 1962 added an important tool to the analytical acoustical arsenal.¹ It was found that the reduction of noise between offices did not alone correlate with acceptability or privacy. It was formulated that background sound, specifically steady-state sources such as fan noise from ventilation systems that did not vary or carry their own messages, were a significant factor in achieving acceptability to office workers for their privacy. Higher levels of background sound provided a speech-masking effect. Lower levels of background sound meant that intrusive noise was much more noticeable and annoying. The role of background sound was quantified, and privacy was correlated with signal-to-noise ratio, not with just noise reduction of construction. This relationship is stated as

$$\begin{aligned} \text{Speech privacy} &= \text{Noise reduction} \\ &+ \text{Background sound pressure levels} \end{aligned}$$

This is the framework for the current evaluation of office acoustics for both closed- and open-plan offices.

3 EFFECT OF ACOUSTICS ON HUMAN PRODUCTIVITY

Acoustics profoundly impacts human performance and has been objectively measured in office settings for its effect on productivity. In fact, numerous demonstrations of these impacts on office workers have been a concern for research scientists for decades, some work going back almost 80 years.² In addition to the focus on productivity, there is currently a strong concern for privacy. This has recently acquired much broader relevance due to a sensitivity to privacy as a civil right and the passage of numerous privacy protection laws by foreign countries (e.g., EU Directive 95.46) and at the federal level in the United States. For instance, with regard to an individual's health records, current legislation in United States requires that the transfer of health records, in whatever format, conform with requirements for privacy (e.g., the Health Insurance Portability and Accounting Act, HIPAA). This includes privacy for digital transfer of health records between providers of health care and presumably *aural* privacy as well. Similar concerns are entering the realm of potential legislation for the financial world also (e.g., the Gramm Leach Bliley Act, relating to privacy of financial transactions).

4 NOISE REDUCTION AND ACOUSTICAL FACTORS IN CLOSED OFFICES

Closed offices by definition have walls that extend at least to the ceiling plane and have a door. Ceiling heights can range from 2.5 m (just over 8 ft) up to 4 m (13 ft) and more. Noise sources within a closed office can be conversations on the telephone or conversations between workers and visitors in the same office. These sources become a distraction to the neighboring space.

The analysis of sound transfer between offices follows traditional procedures of source–path–receiver. The acoustical power of the source, the size of the room, and the finishes on the walls and ceiling will all determine the sound energy within the *source* room. Construction systems for the primary and secondary sound *paths* will determine how much sound energy is transmitted to a neighboring space. The primary sound path is the common wall that may or may not have a doorway or window as part of that path. The secondary sound paths include sound transfer through

the ceiling plenum, through gaps and leaks, through common ducts (both supply and return), through openings around pipes, and through exterior lightweight window systems or even through open windows. The background sound pressure level in the *receiver* room will determine the final signal-to-noise ratio and hence effect the resulting speech privacy. See Fig. 1.

Common Wall Existing standard literature in architectural acoustics provides guidelines for typical sound reduction performance of this primary sound path.³⁻⁸ For example, wall constructions with STC 40 are usually thought to have modest to poor ability to block sound and hence provide poor speech privacy. Constructions with performance in the range of STC 50 are more typical of performance that is necessary for confidential speech privacy.

Wall Constructions For typical modern offices, the range of construction options is limited to just the number of layers of gypsum board on the wall, the type of stud framing, and whether or not there is insulation in the cavity of the wall. A single metal stud with a single layer of gypsum board on each side of the stud and no insulation in the cavity will have a performance in the range of STC 40. If the layers of gypsum board are doubled (i.e., two layers on each side), then the overall STC value will increase by about 5 STC points. There is negligible difference between the performance

of the wall with gypsum board that is 12.5 mm ($\frac{1}{2}$ in.) thick or 15.6 mm ($\frac{5}{8}$ in.) thick. Insulation in the cavity of a wall with a single stud may provide an additional 3 to 5 STC points performance. Wood studs instead of metal studs provide a more rigid path for the transfer of sound and will degrade the performance by 3 to 5 STC points. Further improvements above STC 50 require the use of resilient channels or double-stud framing.³⁻⁸

Ceiling Path In modern lightweight buildings, walls often do not extend to the structure. In these cases, the path for sound through the ceiling plenum is the weakest sound path between offices. This sound path is rated by a ceiling attenuation class (CAC) that is analogous to an STC rating. The CAC value is measured in accordance with ASTM (American Society for Testing and Materials) standards and measures the sound transfer from one standard sized office through an acoustic tile ceiling, then into a standard plenum, and then back into the neighboring office again through an acoustic tile ceiling. Mineral fiber acoustic tiles typically have a rating of CAC 35 to 39. CAC values (or STC values for the same configuration) are provided with a 5-point range. In cases where there is a return-air grille in the ceiling so air can be exhausted through the plenum, or where there is a light fixture with openings, the field performance of the ceiling path will be significantly degraded.

Ceiling Path — Noise Control Options Glass fiber ceiling tiles have CAC values too low to be considered as an effective barrier of any kind. Sometimes offices need the high absorptive properties of a glass fiber ceiling (high NRC) and at the same time a high CAC performance. In this case, the suitable choice is a composite acoustic tile that combines high NRC with high STC, such as a layer of gypsum board or mineral fiber acoustic tile to which a finish layer of glass fiber has been surface mounted. Alternatively, it may be necessary to add a plenum barrier above the partition. This plenum barrier must be of a dense material (gypsum board or sheet lead) with an STC value that is sufficient to upgrade the CAC of the ceiling path so it is equal to the STC of the wall. The plenum barrier must also extend over the corridor wall of adjacent offices so as to prevent flanking around the ends of the plenum barrier.

Gaps and Cracks Openings in the wall will obviously degrade the acoustical performance since the STC rating for an opening is 0. Typical open gaps and cracks are the perimeter around an interconnecting door, gaps at window mullions, open doors to a common corridor, and pipe and duct penetrations that are not sealed airtight.

Other Flanking Paths Sound also travels between adjacent closed offices through lightweight building elements that are common to both rooms. In modern buildings, these flanking paths include lightweight strip windows, curtain walls, common floors, and exterior walls.

Figure 1 Closed office sound paths: (a) continuous strip window, (b) through wall, (c) open doors, (d) interconnecting duct, (e) through plenum, (f) over partition, and (g) gaps at partition.

Composite Constructions In looking at the performance of a common wall between offices, or in evaluating multiple paths that include flanking paths and ceiling paths, often it is necessary to consider the composite effect of the wall elements. Doors and interior windows are notorious for their ability to degrade the acoustic performance of the composite wall. The overall noise reduction of a composite construction is dependent on (a) the performance or STC rating of the weakest path, (b) the STC rating of the primary wall construction, and (c) the area of the weaker path relative to the surface area of the primary construction.

Field versus Laboratory Performance As with any construction system, the actual in-field performance seldom approaches the theoretical or laboratory STC rating for the construction. This is due to flanking paths, field conditions, poor construction practices, and lack of caulking. Noise reduction is measured in the field by a noise isolation class (NIC). Typically, the NIC value will be 5 to 10 points less than the STC rating of a given construction.

Demountable Walls Some offices use so-called demountable walls that have the physical attributes of permanent walls, but the walls can be removed and relocated, thus providing a degree of flexibility that is not available with gypsum board walls and traditional stud construction. These walls extend only to the underside of a continuous ceiling, so the field NIC performance of the wall is usually quite a bit less than its laboratory STC rating.

Background Sound Pressure Levels The background sound pressure level has a strong impact on the degree of speech privacy that can be achieved in closed offices. If the ambient sound is very quiet, NC-30 or less, then even very good constructions can be inadequate to provide privacy. If the ambient is rather loud, NC-40 or above, then even very poor constructions can provide adequate normal privacy. Ambient sound can be contributed by traffic outside, by a central ventilation system, by unit ventilators or fan coil units in the office, or by an electronic sound-masking system.

Ambient noise can also be a source of distraction, as may be the case from exterior noise sources reflecting from adjacent buildings or reverberating from interior courtyards. In these cases, the open windows are often the controlling sound paths, and attention must be paid to the sound transmission from exterior sources through the building envelope. The problems can be exacerbated by U-shaped building configurations in urban environments.

Measure of Privacy As noted above, the relationship between privacy, noise reduction, and background sound pressure levels is indicated in the following relationship:

$$\begin{aligned} \text{Speech privacy} &= \text{noise reduction} \\ &+ \text{Background sound pressure levels} \end{aligned}$$

In one design approach, this general relationship has been transformed into a quantifiable formula:

$$\text{SPI} = \text{NR} + \text{NC}$$

where SPI = speech privacy index

NR = noise reduction, measured as an NIC rating.

NC = measured noise criteria rating

Source room levels are assumed to be normal voice level and normal office sizes. SPI values of 75 or above relate to *confidential* speech privacy, which is a condition where a listener is not able to understand speech from a neighboring office when a talker is using normal voice level. SPI values of 68 to 75 relate to *normal* speech privacy, where only occasional words would be intelligible. SPI values below 68 do not provide speech privacy.

5 NOISE REDUCTION AND ACOUSTICAL FACTORS IN OPEN-PLAN OFFICE

Open-plan offices are characterized by the absence of fixed walls, partitions that do not extend full height to the ceiling, and no doors. These layouts were developed first in the 1960s to provide flexibility in office arrangements, cost savings in office construction, and innovative patterns of work flow. Activities in open-plan offices include the full range of traditional office work activities. These may require (but seldom attain) confidential speech privacy between adjacent spaces or just freedom from distraction.

Although specific layouts may vary dramatically, open-plan offices are the predominant format for office layout today. The offices may have a traditional cubicle format or may be a new "team space" concept. The workstation may be surrounded by stand-alone screens, walls, office furniture, modular workstations, or no barrier whatsoever. Open-plan offices are considered to be less expensive and less costly to rearrange than closed offices. However, because workstations or cubicles do not have full-height partitions, lack of privacy and increased distraction make office workers less productive, as discussed earlier above. Acoustics is an extremely important aspect of open-plan office design and has been an issue of concern since the inception of open-plan office design.^{9,10}

5.1 Privacy Metrics

Articulation Index Speech intelligibility and acoustics in open-plan offices can be rated in terms of articulation index (AI). (See Appendix.) AI is a frequency-weighted measure of the ratio between a signal (e.g., a talker in a classroom, a neighbor's voice, or some intrusive speech) and steady background noise (ambient noise from mechanical equipment, traffic, or electronic sound masking). The frequency ratings reflect the fact that certain octave bands are more important than others for their contribution to speech intelligibility. AI was originally developed to evaluate communication systems and has been widely applied to assess

conditions for speech intelligibility in rooms. AI values range from near 0 (very low signal and relatively high noise; poor intelligibility and good speech privacy) to 1.0 (very high signal and rather low noise, excellent communication and no speech privacy). When privacy is desired (e.g., in an office), it is necessary to have a low AI. When communication is desired (e.g., in classrooms or teleconference rooms), it is necessary to have a high AI so people can understand speech clearly.

Speech Intelligibility Index To some extent, AI is being replaced by the speech intelligibility index (SII) in acoustical standards for office acoustics. (See Appendix.) SII is still, like AI, a weighted-speech-to-noise-ratio. However, it is somewhat more complex to calculate than AI and includes revised frequency weightings and the masking effect of one frequency band on nearby frequency bands. Like AI, it has values that range between 0 and 1, but for the same conditions SII values are a little larger than AI values. An empirical relationship has been developed that allows one to approximate a correlation between AI and SII by two simple adjustment factors.¹¹

Privacy Index Low AI numbers indicate a higher degree of privacy. Since this may be confusing to laypersons who want to focus on better privacy conditions, a new metric called privacy index (PI) has been developed. The privacy index is defined as

$$PI = (1 - AI) \times 100, \text{ presented as a \%}$$

where PI = privacy index

AI = articulation index

In this manner, *higher* PI numbers indicate more privacy; lower PI numbers mean less privacy. For example, an AI of 0.10 equals a privacy index of 90%.

Confidential and Normal Privacy General accepted practice today for design of open-plan offices refers to two levels of speech privacy. *Confidential privacy* is defined as a condition where there is no phrase intelligibility but some isolated word

intelligibility. *Normal privacy* allows modest amounts of intelligibility, but normal work patterns are usually not interrupted. These terms are codified in ASTM 1374 Standard Guide for Open Office Acoustics and Applicable ASTM Standards. (See Appendix.)

Recommended Values Average noise requirements for various office functions are shown in Table 1.

5.2 Analysis Tools

As with any acoustical analysis, open-plan office acoustics can be addressed in terms of the *source* (people talking), the *path* (direct line of sight, barrier effects, reflections) and *receiver* (location of listener in relation to the source and contribution of sound masking). Following is a discussion of factors that influence privacy in open-plan offices (Fig. 2).

5.3 Source

Level Values for typical voice levels have been standardized in American National Standards Institute (ANSI) S3.5 Methods for the Calculation of Articulation Index. (See Appendix.) However, recent research has shown that the occupants of open-plan offices often speak at lower than normal levels, and this has to be taken into account in an analysis of open-plan acoustics. Speech levels in open-plan offices are typically 3 dB to 10 dB quieter than the typical levels from ANSI standards. This is probably due to the increased sense of exposure that talkers have. If a talker can hear others, that talker will sense that he or she can be heard by others. This naturally develops a sense of office etiquette that should be encouraged. It promotes lower voice levels in open areas and suggests to workers that they should relocate to closed offices when having more active (louder) discussions or when increased privacy is required or when using speaker phones.^{11,12}

Orientation The human voice has directional characteristics. Noise levels behind a talker can be up to 10 decibels quieter than levels on axis with the direction of a person talking. However, since the orientation to which a person will be talking is seldom in only one

Table 1 AI, SII, and PI for Open-Plan Offices

AI Value	SII Value	Privacy Index	Criteria Definition	Noise Requirements
>0.65		<35%	Good communication	Necessary when communication is desirable (conference rooms, classrooms, auditoriums, etc.)
0.35		65%	Freedom from distraction	Reasonable work conditions not requiring heavy concentration or speech privacy; can hear and understand neighboring conversations
0.20	0.27	80%	Normal speech privacy	Only occasional intelligibility from a neighbor's conversation; work patterns not interrupted
<0.05	<0.10	>95%	Confidential speech privacy	Aware of neighbor's conversation, but it is not intelligible

Figure 2 Open-plan office sound paths: (a) reflections off ceiling, (b) reflections off light fixtures, (c) diffraction over partial height barrier, (d) through barrier, (e) around end of barrier, (f) secondary reflections, (g) sound masking from loudspeakers above the ceiling, and (h) sound masking from direct-field emitters.

direction, and since an office often has reflecting surfaces in front of a talker, most models of acoustics in open-plan offices do not account for this factor.

Office Layout and Size The size of an office indirectly determines the distance from a source to the nearest barrier and thus effects the barrier effect and also the distance to the receiver. Space for an office is often the single most expensive element in the design, and there is strong pressure to reduce office cubicle size in many situations. A normal office might be in the range of 3 m × 3 m (10 ft × 10 ft) but some conditions can be as small as 2 m × 2 m (6.6 ft × 6.6 ft) or 2.5 m × 2.5 m (8.2 ft × 8.2 ft).

5.4 Path

Barrier Effect (Screen Height) Partial height barriers or partitions are necessary to block direct sound transmission between workstations. If there is no barrier, the direct path will govern the sound transfer and, unless there are extraordinary distances between source and receiver, speech privacy will be unattainable. The barrier must be high enough and wide enough to interrupt the line of sight between

a source and a receiver. The height of the mouth of a talker and the ear of a listener is normally about 1.2 m (4 ft) above the floor. Hence, the first 1.2 m (4 ft) or so of barrier height do not help speech privacy at all, and barriers or partitions need to be significantly higher than this height so as to be able to block sound. This means a barrier must have a height of about 1.5 m (5 ft) as a minimum requirement for acoustical separation, and a height of 1.8 m (6 ft) typically for normal privacy. Above this height there are diminishing returns because of reflections off the ceiling and diffraction over the barrier.¹³

Barrier Absorption The absorption on the surface of a barrier does not have any direct effect on the sound transfer between the neighboring workstations except if there are secondary reflections off barriers on the other side of the cubicle. It is good practice to reduce these reflections, and even modest NRC values of 0.65 for the inside surface of a cubicle can be beneficial.

Barrier Transmission Loss The barrier should be able to block sound at least as well as the path for sound diffracting over the barrier, which means a minimum laboratory sound transmission class value of STC 20. This is more than adequate. Barriers or screens should extend to the floor or leave only a small opening at the bottom. There should be no open gaps between adjacent panels. Values higher than STC 20 are of no additional benefit.

Barrier Location A barrier is most effective if placed close to the source or receiver.

Ceiling Absorption The ceiling in an open-plan office is the most important surface to treat with highly efficient sound-absorbing material. The ceiling should have a noise reduction coefficient (NRC) of at least 0.90 or an articulation class (AC) of at least 180. These terms are described further below. A ceiling with absorption properties lower than these may make privacy less than acceptable. A ceiling with absorption properties higher than these can be of more benefit since it may help mitigate the adverse contribution of other less effective components. Therefore, glass-fiber ceiling panels, which typically have high absorption properties, are the preferred material for ceilings in open-plan offices. Regular mineral-fiber acoustical panels have typical NRC value of only about 0.55 to 0.65. Hard sound reflective materials such as exposed structure or gypsum board have NRC values less than 0.10 and will dramatically reduce privacy and raise annoying sound pressure levels in an office. Most ceiling tile manufacturers provide extensive data on the sound absorptive properties of their products and will have special products for use in open-plan spaces. Materials must also be selected for their ability to reflect light.

NRC, SAA, and AC The sound absorptive performance of acoustical ceilings can be determined in either of two ways. One process is the measure of

sound absorption coefficients in a reverberation chamber in accordance with ASTM C423. (See Appendix.) This determines the random incidence sound absorption coefficients (α) for the test material. From these data, manufacturers typically report the NRC. The NRC value is a good first approximation of the ability of a material to absorb sound in the human speech range. NRC is the average of coefficients of absorption for four mid-range frequencies (250 Hz, 500 Hz, 1000 Hz, and 2000 Hz), rounded to the nearest .05. NRC values range from 0 to 1.

$$\text{NRC} = \frac{\alpha_{250} + \alpha_{500} + \alpha_{1000} + \alpha_{2000}}{4}$$

(rounded to nearest 0.05)

Another term gaining increasing application is the sound absorption average (SAA). SAA is a single-number rating that is the average, rounded off to the nearest 0.01, of the sound absorption coefficients of a material for the 12 one-third octave bands from 200 through 2500 Hz. The SAA can be used in conjunction with NRC rating. (See Appendix.)

In an open-plan office, the actual effectiveness of the ceiling in determining noise reduction is related to its absorptive performance and the height of the barrier that separates two workstations and the distance between a talker and listener. Therefore, another term has been developed for a measure of the ceiling's contribution to noise reduction between typical (but specifically designated) workstations. This is the articulation class (AC), measured in an office mockup environment in accordance with ASTM E1111 and E1110. (See Appendix.) AC values range from about 150 to 220. The AC is the sum of the weighted sound attenuation numbers in a series of 15 test bands for a carefully specified office layout, barrier height, and ceiling height.

Ceiling Height The height of a ceiling also impacts its effectiveness in open-plan office acoustics. Typical ceiling heights might be in the range of 2.7 m (8.8 ft). Lower ceilings will have a noticeable adverse impact on privacy because sound reflected off the ceiling will be at a higher sound pressure level. This is due to the shorter sound path of the reflected sound energy, which increases the level of the disrupting signal, increases the signal-to-noise ratio, increases the AI, and therefore reduces the privacy index. The lower the ceiling, the more important the absorptive properties are for controlling reflections and providing speech privacy. Higher ceilings do not make a radical improvement, unless you go to significantly higher spaces with 5.4-m (18-ft) ceilings or above. Such very high ceilings of hard sound-reflecting materials will increase overall noise levels but may not degrade speech intelligibility.

Wall Reflections Reflections and diffraction around the ends of a partial-height partition also must be taken into account. In particular cases where such reflections are detrimental to the desired low AI, the

wall reflections should be eliminated. This can be done with the closure of a panel tight against the wall (hence eliminating the flanking path around the end of the panel altogether), or there should be additional sound-absorbing material at the offending sound-reflecting wall. This can be analyzed with a relatively simple ray diagram. To be effective in reducing sound energy from the offending reflecting surface, the additional material should have an NRC value of 0.80 or higher.

Ceiling Reflections Sometimes elements in the plane of the ceiling may degrade speech privacy because they reflect sound from one workstation to another. In particular, flat lens light fixtures act as acoustical mirrors and should be avoided, especially if the fixtures are aligned right over the partial-height wall.

Office Layout Office layout also affects speech privacy. Offices should be arranged so that entrances are offset, and direct line of sight or an open view through doorways from one workstation to another should be eliminated. Workstations should be 2.45 m by 3.0 m (8 ft to 10 ft) apart so voice levels are adequately reduced over distance (see Fig. 3).

Floor Carpet, whether thick or thin, is very helpful in an open-plan office because it reduces footfall noise, eliminates the sound of moving chairs, and cuts down on any reflected sound that bounces between spaces off hard floor surfaces. However, carpet is of very little direct benefit in actually absorbing sound in the office.

5.5 Receiver

Background sound can be generated by a ventilation system, by outdoor traffic noise (at least for offices closest to exterior windows), or by an electronic system. There are many advantages of an electronic system. It can provide a preferred sound pressure level and spectrum. It will not vary depending on the outside temperature or inside heat load. It can provide evenly distributed coverage throughout an office while a ventilation system may be too loud near diffusers and too quiet elsewhere.

In concept, an electronic sound-masking system comprises a noise generator, spectrum shaper with filters, amplifiers, and loudspeakers. Many systems use loudspeakers hidden above a suspended acoustic tile ceiling. The sound pressure level and spectrum for these plenum loudspeakers are then adjusted until the desired effect below the ceiling at the workstation is achieved. Other newer technologies use loudspeakers directly in the plane of the ceiling that do not need any spectrum adjustment.

6 SOUND-MASKING TECHNOLOGY AND DESIGN

Masking Sound Spectrum The character and level of background sound is perhaps the most important acoustical design consideration for an open-plan office. A modest level of background or ambient sound will cover, or mask, annoying intrusive sounds.

Figure 3 Open-plan office layout configurations: (a) poor layout, (b) fair layout, and (c) better layout.

The masking sound must be pleasant and neutral with an even tonal spectrum (like the sound of a comfortable ventilation system) that drops off at the

high end of the frequency range. There should be no pure tones or annoying characteristics (like the humming sound of a fluorescent light ballast). A sample spectrum that is well accepted is shown in Fig. 4. There are variations on this spectrum that are also acceptable.¹⁴

Masking Sound Pressure Levels The sound should be evenly distributed throughout the office so the sound is no louder in some areas than others. In addition, the generally accepted practice is that the level should not vary in the open-plan area by more than 3 dB in any octave band. Masking sound should be loud enough to cover intrusive noises, but never loud enough to be distracting in itself. Many studies have concluded that the preferred range of A-weighted sound pressure levels is perhaps between 45 and 50 dB.¹⁰ Conference rooms and private offices require lower levels of background sound for ease of communication within the room.

Use of HVAC Systems as Masking Sound Source

In theory, normal air-conditioning and ventilation systems could generate appropriate background noise to mask speech between offices or workstations. To do so, the ambient sound from the heating and ventilation system would have to be of the correct loudness, acceptable spectrum (frequency distributions), steady and constant throughout the day, and uniformly distributed spatially throughout the office. This is seldom the case. Heating, ventilating, and air-conditioning (HVAC) systems are not designed for this purpose. Many office buildings use variable volume air distribution, so noise from the HVAC system may be erratic and uneven in distribution, and it may change in level over time and season. Mechanical engineers usually design office mechanical systems to provide typical

Figure 4 Desired spectrum and level for background sound (speech masking) in open-plan offices.

operating A-weighted sound pressure levels from 5 to 10 dB below the desired range for masking sound. Diffusers are placed for air distribution concerns, not for acoustics. All in all, the HVAC system cannot be relied upon to meet the speech-masking needs of offices.

Electronic Sound-Masking Systems—Loudspeakers above Ceiling Traditional sound-masking systems have used loudspeakers installed above the office ceiling, hidden above an accessible acoustic tile or panel. This type of system must have the ability to adjust the spectrum easily in order to provide the correct frequency distribution. The system must generate enough power to transfer adequate sound energy through the ceiling panel. And the system must be designed to assure even spatial uniformity for the occupied office space. Even a 3-dB variation from one workstation to another can have a dramatic effect on speech privacy. Without the benefit of even spatial distribution, a system may be either operated at a level that is so loud that it causes annoyance to many users, or conversely may be operated at a level that is so low that it does not provide good privacy throughout the office.

The design of these above-ceiling systems is made more difficult because of the sound attenuation characteristics of typical ceiling and plenum materials, openings for return-air trough diffusers and light fixtures, and reflections off structure or ductwork in the plenum. Theoretically, there are some measures that can be taken to mitigate the design problems, such as providing each loudspeaker with a volume control, using many more loudspeakers, and providing sound attenuating “boots” at each opening in the ceiling. Realistically, however, these measures are rarely employed because of the resulting costs.

Electronic Sound-Masking Systems—Loudspeakers below Ceiling New technology uses sound-masking emitters (loudspeakers) in the plane of the ceiling, so-called direct-field emitters that radiate sound directly into the occupied space below, rather than into the above-ceiling plenum. In this manner, the system may provide much better uniformity of masking sound throughout the open-plan office. The principal advantage of direct-field emitters is that there is no nonuniformity caused by HVAC openings in the ceiling or ventilation slots in lighting fixtures, or by building structure, fireproofing, and large ducts or other mechanical components in the plenum. Such anomalies no longer have any significant effect on the spatial distribution of masking sound in the office. The system designer can assure very uniform coverage simply by providing a well-defined and simple layout of masking loudspeakers, without a precise knowledge or consideration of above-ceiling building elements.

Another significant advantage of direct-field emitters is that these systems also assure that the frequency distribution of sound is optimum because there are no significant frequency-dependent acoustical attenuators between the loudspeakers and office occupants.

No spectrum adjustments are necessary in the field. To the user, this means that the system is able to provide effective masking at considerably lower sound pressure level and lower potential for annoyance, and that the acoustical effectiveness is maintained throughout the building.

Also, the direct-field emitters beneath the ceiling require lower power level than required for above-ceiling loudspeakers since they are radiating directly into the sound field, not into a plenum. However, the loudspeakers need to be quite omnidirectional except at the very highest frequencies.

Because of these acoustical advantages as well as economic factors, these systems are gaining increased acceptance in the marketplace. To be acceptable visually, however, the loudspeakers will either have to look like a ceiling acoustic tile or will have to be very inconspicuous.

Electroacoustic Issues Experience has found that having incoherent masking sound from multiple channels reduces the chance of localization or peaking due to phase interference or phase amplification. Some systems have up to four incoherent channels to avoid interference effects.

7 METHODS FOR CALCULATING ARTICULATION OR PRIVACY INDEX

Acousticians have been developing unified theories and programs to combine the different aspects of open-office acoustics into a reliable predictive methodology. The systems vary from simple worksheets to complex computer programs, and they have been developed to combine the effect of these variables and to assign an estimated AI value to a particular layout or range of materials. In this way, the influence of each parameter of the office design on the expected speech privacy in the office can be determined ahead of time. Pertinent variables include all the items noted above to varying degrees, such as the ceiling absorption, the height of partial height panels, and the workstation plan size are shown to be most important.⁹ The success of any of these analysis tools depends on the correctness of the model and the accuracy of the assumptions on which it is based.

8 OFFICE MACHINERY

Other equipment in a typical office should also be identified and treated appropriately to reduce annoyance and distraction to nearby workers. This equipment includes copiers, telephones, collators, paging systems, and other sources that are distractions. Copiers are best located in a separate alcove or preferably in a separate room with a door, and with sound-absorptive materials close to the cooling fans, which are the predominant noise source.

9 FUTURE DEVELOPMENTS

Although open-plan schools have been found to be inappropriate for teaching environments, open-plan offices will undoubtedly remain an important part

of office layout and design. Acoustics is a major concern. Masking is a critical component of good privacy and freedom from distraction; its vital role for speech privacy and productivity has gained increasing recognition. We can expect to see greater use of easy-to-install sound-masking systems, perhaps brought right to the desk-top workstation, perhaps integrated directly into furniture systems.

APPENDIX STANDARDS RELATED TO PREDICTING, EVALUATING, AND MEASURING SPEECH INTELLIGIBILITY AND PRIVACY PARAMETERS USED IN ACOUSTICS DESIGN OF OFFICE WORK SPACES AND OPEN-PLAN OFFICES

ANSI (American National Standards Institute)	
S3.2	Method for Measurement of Monosyllabic Word Intelligibility
S3.5	Methods for the Calculation of Articulation Index
ASTM (American Society of Testing and Materials)	
E-90	Standard Method for Laboratory Measurement of Airborne Sound Transmission Loss of Building Partitions
E-1041	Guide for Measurement of Masking Sound in Open Offices
E 1110	Standard Classification for Determination of Articulation Class
E 1111	Standard Test Method for Measuring Interzone Attenuation of Ceiling Systems
E 1130	Standard Test Method for Objective Measurement of Speech Privacy in Open Offices Using Articulation Index
E 1179	Specification for Sound Sources Used for Testing Open Office Components and Systems
E 1374	Standard Guide for Open Office Acoustics and Applicable ASTM Standards
E 1375	Standard Test Method for Measuring the Interzone Attenuation of Furniture Panels Used as Acoustical Barriers

E 1376	Standard Test Method for Measuring the Interzone Attenuation of Sound Reflected by Wall Finishes and Furniture Panels
C 423	Standard Test Method for Sound Absorption and Sound Absorption Coefficients by the Reverberation Room Method
ISO (International Standards Organization)	
60268-16	Objective Rating of Speech Intelligibility by Speech Transmission Index
9921-01	Speech Interference Level and Communication Distances for Persons with Normal Hearing Capacity in Direct Communication (SIL method)

CHAPTER 109

ACOUSTICAL GUIDELINES FOR BUILDING DESIGN AND NOISE CONTROL

Chris Field

Arup Acoustics San Francisco
San Francisco, California

Fergus Fricke

Faculty of Architecture Design and Planning
University of Sydney
Sydney, New South Wales, Australia

1 INTRODUCTION

In the acoustical design of buildings, consideration must be given to the location, the user requirements, the primary function of the building, and the budget available. The acoustical requirements for buildings can vary greatly according to the intended use of the individual spaces that may include speech, music, sports, and art exhibitions. Compatibility with nonacoustical requirements such as structural integrity, building services, and ventilation standards is also essential.

Acoustical design and noise control guidelines are available for various buildings, including performance spaces, offices, dwellings, art galleries, sports halls, hospitals, churches, and conference facilities. To determine acoustic and noise control requirements, a methodical approach is required.

International sound isolation and room acoustic standards are available and appropriate acoustical treatments and sound insulating constructions should be utilized to meet these standards.

2 METHODOLOGY FOR DETERMINING ACOUSTIC AND NOISE CONTROL FOR BUILDINGS

When determining the acoustic and noise control requirements in the design of buildings, the following steps can be used to ensure all acoustic requirements and standards are dealt with:

1. Review the range of uses of the building.
2. Review the building location in relation to any adjacent noisy or noise-sensitive spaces.
3. Set the appropriate background noise level design target for the building.
4. Set the room acoustic requirements/qualities for the building. This includes compliance with the relevant building codes and standards.
5. Assess the proposed internal geometry for the building with the required shape to optimize acoustics.
6. Calculate the room acoustic requirements, including amount and placement of acoustic treatment necessary to meet design targets.

7. Calculate the required level of sound isolation of the building with respect to steps 2 and 3.

The following sections describe in detail the methodology required in each of the above steps. Calculations of building services noise levels should also be carried out to ensure the resultant levels are compatible with the background noise level targets. Calculation methodology for building services noise control is given in Chapter 111.

2.1 Range of Uses of the Building

Ever increasing construction costs and limited financial budgets often mean that a particular building must cater for different uses. An example is the so-called multipurpose hall where the uses may include dramatic theater, symphonic music, amplified contemporary music, conferences, seminars, and trade shows. Each of these uses has its own set of acoustic requirements that often conflict.

Therefore, one of the first steps in the acoustic and noise control design of a building is to establish the range of uses of the building. By carrying out this assessment, conceptual acoustic design elements to fulfil the requirements of the building can be included from the beginning of the building design. These elements may include variable acoustic treatment systems, temporary acoustic shells, or the ability to increase or decrease the physical volume of the building to alter the acoustic characteristics.

2.2 Review of Building Location

A review of the building location in relation to external noise sources, or the location of acoustically sensitive spaces relative to noise-generating spaces within a building, must be carried out.

For existing external noise sources, such as ground transport traffic or railway systems, a noise survey should be carried out to quantify the intrusive noise levels incident on the proposed building. These noise levels can be used as the basis for determining sound isolation requirements for the building facade.

For any proposed internal noise sources, such as equipment located in plant rooms, manufacturer's

noise data for the proposed plant should be obtained. These equipment sound pressure levels would be used as the basis for determining sound isolation requirements for separating constructions of walls or floors to prevent noise intrusion to the acoustically sensitive areas of the building.

2.3 Background Noise Level Targets in Buildings

Excessive background noise can create a distracting and annoying working environment, lead to poor concentration, and result in poor productivity. In performance spaces, it can impair the acoustic enjoyment of a performance. Note, however, a reasonable level of background noise, with an appropriate frequency spectrum shape, can enhance speech privacy in offices by masking intrusive noise from adjacent spaces.

The source of background noise in buildings is generally from building services such as plant, air-conditioning, and plumbing systems. Noise break-in from external sources, such as ground transport traffic or aircraft, through facade glazing, roofs, and ventilators can also be significant.

By the careful design of air-conditioning systems, plant rooms, and facade constructions, the background noise level can be controlled to meet commonly recommended criteria in the relevant spaces. These criteria are outlined in Section 3.3.

2.4 Determination of Criteria for Acoustical Quality and Reverberance Control

The calculation of reverberance in a space is important to determine the appropriateness of the space for its use. For example, should the reverberance in a space be too long, speech may be unintelligible or classical music may lack clarity. Conversely, should the reverberance be too short, speakers may have to strain their voices to reach the rear of the space and instrumental pieces may sound dead.

Multiple reflections are normally assessed in terms of the reverberation time, which is the time taken for the sound pressure level to decay by 60 dB after the source output ceases. The reverberation time of a space can be easily measured using appropriate instrumentation. Reverberation time criteria for various spaces are given in Section 3.2. In addition to reverberation time, there are many other parameters used to describe the acoustic quality of spaces. The design of musical performance spaces, for example, includes parameters to quantify the clarity of instrumental sound, warmth, ensemble, and listener envelopment. Barron¹ and Beranek² provide detailed information into the parameters used in the specialist acoustic design for performance spaces.

2.5 Sound Isolation Requirements

To achieve speech privacy ratings, and also to generally control noise intrusion to sensitive spaces, adequate sound isolation performance from the building facade and internal partitions must be achieved.

Design standards for residential buildings are well documented in various international codes, as discussed in Section 3.3. Recommended standards are also presented for other building types.

On-site construction of partitions is a critical consideration since sound isolating ratings (STC/R_w) are based on laboratory tests under ideal conditions. This performance is rarely met on-site due to constraints on workmanship and noise flanking paths (see Chapter 115).

2.6 Review of Internal Building Geometry

The internal geometry of buildings has a significant effect on the acoustical quality of the space. Performance spaces such as concert halls, for example, rely on the shape and size of the stage enclosure and auditorium to project instrumental sound to the audience. Therefore, at the conceptual stage of the building design, suitable internal geometry should be defined to suit the use of the space. Guidelines for various building uses are given in Section 4.5.

2.7 Calculations to Determine Room Acoustic and Noise Control Requirements

Once the design targets and user requirements have been established, calculations to determine room acoustic and noise control requirements can be carried out. For room acoustics, there are several methods for predicting the reverberation time in a building.³

For calculation of sound isolation requirements, an equation based on the calculation of the reverberant sound field in an internal space can be used.³ These methods are presented in Section 4.2.

3 ACOUSTICAL DESIGN CRITERIA AND REQUIREMENTS FOR BUILDING SPACES

3.1 Suitable Internal Background Noise Level Targets

British Standard 8233:1999⁴ and Australian Standard 2107⁵ provide reasonable guidance for design background noise levels for various types of occupancy. The limits apply to steady-state or quasi-steady-state sounds such as noise from air-conditioning systems and are given as overall A-weighted sound pressure level limits for many room types.

Noise criterion (NC) or NR curves are commonly used as an alternative or a complement to A-weighted sound pressure level values for the specification of services noise limits because they allow noise levels with a “balanced” frequency content to be achieved. NC curves were derived from interviews with users of buildings with various noise environments with noise measurements made in occupied rooms with building services systems operating normally. NC values are defined by a series of curves that give noise level limits in octave bands across the frequency range of human hearing. Chapter 106 provides details of NC curves and other noise criterion curves (NR, PNC, NCB) used for internal spaces.

The use of NC curves is recommended for the control of building services noise levels. For common building services noise spectra, the NC rating is

Table 1 Examples of Recommended Target Noise Limits in Spaces

Area	Recommended Internal Noise Level Targets
Concert halls	NC 15–20
Theaters	NC 20–25
Art galleries	NC 25–30
Sports halls	NC 40
Open-plan office/workstations	NC 40
Enclosed/private offices	NC 35
Conference/large meeting rooms	NC 30
Meeting rooms	NC 35
Video conference rooms	NC 25
Cafeterias	NC 45
Store/utility spaces	NC 45
Office break-out areas	NC 45
Undercover carparks	NC 60
Plant rooms (excluding chiller/generator)	NC 65
Lift motor rooms	NC 65

typically 5 dB below the equivalent A-weighted sound pressure level [e.g., a noise limit of NC 30 is approximately equivalent to an A-weighted sound pressure level of 35 dB].

Typical target noise limits for steady-state noise generated by building services and noise break-in from external sources have been determined by a combination of guidance from BS8233, AS 2107, and conditions in existing buildings. Table 1 outlines noise level targets for the various spaces to be achieved by all services running normally and together plus external noise break-in. Chapter 115 provides targets for other noise-sensitive spaces.

3.2 Room Acoustic Requirements

Guidance for suitable reverberation times for various types of spaces can be found in AS2107-2000,⁵ BS8233-1999,⁴ and Lawrence.⁶ Table 2 presents

Table 2 Examples of Recommended Mid-Frequency Reverberation Times for Various Spaces

Space	Typical Mid-Frequency Reverberation Time (500–1000 Hz) in Seconds
Churches	2.5–5.0
Concert halls	1.5–2.3
Conference/meeting rooms	0.6–0.8
Sports halls	1.5–1.8
Multipurpose halls	0.9–1.6
Offices	0.4–0.9
Swimming pools (indoor)	1.3–3.0
Theaters	0.6–1.5
Art galleries	1.0–1.4
Open-plan office/workstations	0.6–0.8
Cafeterias	1.0–1.5

examples of typical mid-frequency reverberation time objectives for various spaces.

3.3 Sound Isolation Performance of Building Elements

The sound isolation performance of partitions is usually limited by flanking paths, penetrations, and air gaps in and around the partition rather than a weakness in the construction itself. Typical partition constructions and their ideal sound isolation performances are presented below. Information on other transmission paths, which weaken the acoustic performance of partitions, is also given to serve as guidance during the design process.

3.3.1 Residences National building codes specify minimum sound isolation requirements between various habitable spaces in dwellings. Several national building codes are currently being reviewed due to the general acknowledgment that the current codes do not provide satisfactory standards on internal sound isolation. For guidance, a general summary of suitable sound isolation ratings for control of internal noise within residential dwellings, using relevant information from German,⁷ Australian,⁸ and Nordic standards^{9,10} is given in Table 3. Noise regulations in U.S. building codes vary greatly according to particular states and localities. Tocci¹¹ presents a general discussion of noise control in U.S. building codes.

3.3.2 Performance Spaces and Recording Studios The sound isolation requirements for performance spaces and recording studios are generally very high, due to the requirement to have very low background noise levels in these spaces. The requirements, however, are highly dependent on the desired quality of the space in relation to the available budget. To meet these generally high isolation standards, space planning is an important aspect of the design process.

In performance space buildings, sound lobbies with multiple door sets are used as buffers to external noise intrusion. Structural isolation of critical areas such as the auditorium is typically carried out. The building

Table 3 Summary of International Guidance on Suitable Sound Isolation for Control of Internal Noise within Residential Dwellings

Separating Construction	Airborne Sound Isolation Requirement (STC/ R_w)	Impact Sound Isolation Requirement ($L'n, w$)
Floors between dwellings	54–58	46–53
Party walls between dwellings	53–58	46–53
Walls between dwellings and hallways/stairwells	52–58	48–58
Walls between dwellings and bathrooms/kitchens in adjacent dwellings	53–58	46–53

envelope is generally a high-density concrete or solid-block work construction.

In recording studios, the studio box is often structurally isolated using a “box-in-box” construction. Further guidance in the design of recording studios can be obtained from the *British Broadcasting Corporation Guide to Acoustic Practice*.¹²

3.3.3 Office Buildings Acoustic privacy in offices, or other spaces used for speech, is affected by several parameters, including:

- The level of intrusive speech in the originating space
- Background noise levels in the “receiving” areas
- Sound isolation provided by partitions or screens separating adjacent areas
- Sound absorption within the space

The higher the level of background noise in the receiving room the greater the speech privacy in that room. Conversely, lower background noise levels provide less speech privacy and require partitions with higher sound isolation to achieve the same level of privacy.

A balance must be struck between the level of background noise that can be accommodated without being disturbing to the occupants and the level of sound isolation that can be reasonably achieved by the partition. For example, conference rooms require a relatively low background noise level and, therefore, require partitions with a correspondingly high sound isolation. (Note that to achieve a 5-dB increase in the sound isolation of a partition generally requires a doubling of either the mass of the partition or a doubling of the cavity width). Chapter 115 presents a method of predicting the frequency-dependent transmission loss of partitions based on the partition surface density.

For general occupational noise resulting from speech, a convenient method to assess the level of isolation offered by a particular partition is to allocate each construction a *speech privacy rating*. Table 4 summarizes the different levels of speech privacy classification and their subjective meanings.

It is recommended that the following speech privacy ratings are set as targets in the following room types:

Private offices—Good to very good
Open-plan offices—Fair to good
Classrooms/dance studios—Fair
Meeting/conference rooms—Very good
Video conference room—Very good
Theaters—Excellent

Note that it is not generally possible to achieve these ratings across partitions incorporating doors, due to the difficulty in providing adequate acoustic seals on a door without compromising its ease of use, or providing a lobbied “sound lock” arrangement. Careful planning of door locations is likely to result in more practical outcomes. Table 5 indicates the level of sound isolation of the separating partition and relative to the background noise level in order to achieve the specified speech privacy ratings given above.

3.3.4 Typical Constructions for Controlling Noise Typical partition constructions for achieving sound isolation ratings are given in Table 6. Further examples are given in Chapter 115. It should be noted that the STC/R_w ratings given are laboratory-measured ratings. It is common practice to reduce these laboratory ratings by 5 dB due to site installation constraints.

3.3.5 Doors and Seals Doors will limit the overall sound isolation of a partition since they are generally of much lighter construction than the partition, and they are difficult to effectively seal. While high-performance doors can be provided, it should be understood that they are likely to be heavy, more difficult to operate, and relatively expensive.

Depending on the arrangement of the door, and the relationship of the room to other adjacent spaces, a door with a sound isolation performance considerably less than the partition itself will be appropriate. One must be aware that some contradictions may appear between the acoustical objectives and the safety requirements (e.g., ease of exit preventing the use of an airlock, or fire proofing preventing the use of efficient sealing).

Table 7 gives typical door constructions required in the acoustically rated partitions.

3.3.6 Other Transmission Paths Ceiling Voids For partitions with a sound isolation rating greater than an R_w of 35, noise transfer via the ceiling void can limit the overall sound isolation of the partition. Ceiling void

Table 4 Subjective Speech Privacy Ratings

Speech Privacy Rating	Subjective Description	
	Normal Speech	Raised Voices
Poor	Intelligible	Clearly intelligible and possibly disturbing
Fair	Audible, could be intelligible if speaker and/or subject well known	Intelligible
Good	Audible but not intelligible	Audible, could be intelligible if speaker and/or subject well known
Very good	Just audible	Audible but not intelligible
Excellent	Inaudible	Just audible

Table 5 Speech Privacy Ratings

Normal Speech	Raised Voices	Continuous Listener Background Noise Level			$D_W + NC^a$	Speech Privacy Rating
		NC30 Room-to-Room Level Difference D_W	NC35	NC40		
Intelligible	Clearly intelligible and possibly disturbing	<35	<30	<25	<65	Poor
Audible. Could be intelligible if speaker and/or subject well known	Intelligible	35–40	30–35	25–30	65–70	Fair
Audible but not intelligible	Audible. Could be intelligible if speaker and/or subject well known	40–45	35–40	30–35	70–75	Good
Just audible Inaudible	Audible but not intelligible Just audible	45–55 >55	40–50 >50	35–45 >45	75–85 >85	Very good Excellent

^aNC is defined in Section 4.2.**Table 6 Examples of Typical Sound Isolation Performance of Wall Constructions**

Sound Isolation Performance, STC/ R_w	Wall Buildup
35	<ul style="list-style-type: none"> 10.38-mm laminated glass 1 × 13-mm plasterboard each side of a 64-mm metal stud (total width 90 mm) 100-mm block work (low density 600–900 kg/m³)
40	<ul style="list-style-type: none"> 1 × 13-mm plasterboard each side of a 64-mm metal stud with 50-mm absorptive quilt in cavity 100-mm block work (low density 600–900 kg/m³) rendered 13 mm both sides
45	<ul style="list-style-type: none"> 2 × 13-mm plasterboard each side of a 64-mm metal stud (total width 116 mm) 112-mm fair faced brick (unplastered) 140-mm medium-density block work (1400 kg/m³)
50	<ul style="list-style-type: none"> 2 × 13-mm high-density plasterboard each side of 2 × 64-mm studs offset in 92-mm track with 50-mm absorptive quilt in cavity

Table 6 (continued)

55	<ul style="list-style-type: none"> 224-mm fair faced brick (unplastered) 190-mm medium-density block work (1900 kg/m³) plastered or rendered 13 mm on both side 2 × 13-mm high-density plasterboard each side of staggered 64-mm studs in 92-mm width track with 50-mm absorptive quilt in cavity
60	<ul style="list-style-type: none"> 112-mm fair faced brick each side of a 75-mm air gap, resiliently tied and plastered both sides 2 × 16-mm high-density plasterboard, 2 × 64-mm separate studs, 2 × 16-mm high-density plasterboard with 100-mm absorptive quilt in cavity

barriers, or full-height partitions, should therefore be used for all partitions with a performance requirement greater than R_w 35. The barrier should comprise either mass-loaded vinyl with a minimum surface density of 8 kg/m² or one layer of plasterboard sealed airtight.

Services Penetrations Penetrations through the cavity barrier must be made good with further layers of plasterboard close-cut to the duct or pipe work or further overlapping layers of mass-loaded vinyl. Penetrations must be fully sealed with a polysulfide sealant (for plasterboard), or taped up (mass-loaded vinyl).

Table 7 Examples of Typical Door Construction Requirements in Acoustically Rated Partitions to Corridors and Open-Plan Spaces

Partition Sound Isolation Rating, R_w /STC	Typical Corresponding Door Sound Isolation Rating, R_w /STC	Typical Door Construction and Sealing Arrangement
35	15	Aluminum framed glazed door or hollow-core door with simple frame seals (e.g., self-adhesive)
35	20	32- to 35-mm solid-core door with simple frame seals, threshold close cut to carpet
40	25	35-mm solid-core door with frame seals
45	30	35- to 40-mm solid-core door with frame and threshold seals
50	35	40- to 45-mm solid core door, with high-performance rebated frame and threshold seals, possibly proprietary doorset
55	40	Proprietary acoustic doorset, 50–80 mm with double rebated seals
60	45	Proprietary acoustic doorset, 80 mm with double or triple seals

Mechanical Services Ducts Ducts between offices also have the potential to lower the effective sound isolation between spaces. Cross-talk attenuators may, therefore, be required in ductwork crossing high-performance partitions. The acoustic performance of the cross-talk attenuator should be sufficient to maintain the performance of the ceiling cavity barrier. Beware that attenuators may be proscribed by safety regulations when the duct network can be used for smoke exhaust purposes.

Glazed Partitions They are likely to limit the maximum level of privacy that can be achieved. The typical sound isolation performance of a single glazed partition (10.38-mm laminated glass) is around R_w 35. Consequently, the level of privacy provided via these partitions will be relatively poor. Double-glazed systems may be used and can generally achieve R_w 42 for a standard sealed system.

Operable Partitions They are likely to be the limiting factor for speech privacy in rooms where they are used. This is due mainly to the limitations of the perimeter seals of the demountable wall. The maximum sound isolation performance, of commercially available operable partitions, is claimed by the manufacturers to be R_w 48 to 52—achieving this on-site is particularly challenging.

4 CALCULATIONS FOR ACOUSTIC AND NOISE CONTROL DESIGN

4.1 Acoustic Quality and Reverberation Time

4.1.1 Prediction of Reverberation Time Several methods have been developed to calculate the reverberation time of a space according to its physical characteristics. A comprehensive summary of the methods is given in Beranek.³

The most common equation used in engineering design is the one determined by Sabine. This equation has its limitations (see Beranek³) but gives an easy way of calculating the reverberation time of a space quickly. Sabine's equation is often used in the preliminary stages of a design. As the design of a space progresses, computer modeling techniques are used to obtain a more realistic prediction of

reverberation time (RT), which accounts for location of absorptive materials and unusual sound fields in spaces, both of which are not accounted for by Sabine's equation.

The form of Sabine's equation often used is as follows:

$$RT = \frac{0.161V}{A}$$

where V is the volume of the space (m^3) and A is the total absorption in the space (m^2 sabin):

$$A = \sum S_n \alpha_n$$

where S_n is the surface area of the material having an absorption coefficient of α_n .

Absorption coefficients of common materials are presented in Table 8. Further information on absorption coefficients of various materials can be found in Bies and Hansen.¹³

4.1.2 Shape of Space and Placement of Absorptive Material Sabine's equation gives us an indication of the amount and type of material to be added to the internal surfaces of a space to control reverberance. In addition to providing enough material, the location of the material in the space is also important.

When considering the placement of acoustic absorption in the space, the following attributes of the space should be noted:

- The use of the space (classical music, speech, amplified music)
- The distance between the source and receiver
- The shape of the space

The design of the shape of the space is a very important aspect of acoustic design of auditoria and performance spaces and requires much greater detail than can be presented here. Barron¹ provides further guidance in this aspect of acoustic design.

Table 8 Examples of Absorption Coefficients of Some Common Materials

Material	Octave Band Center Frequency (Hz)					
	125	250	500	1000	2000	4000
Thick carpet on foam underlay	0.08	0.24	0.57	0.69	0.71	0.73
Concrete or terrazzo tile	0.01	0.01	0.01	0.01	0.02	0.02
Medium velour drapes	0.07	0.31	0.49	0.75	0.7	0.6
Glass window	0.35	0.25	0.02	0.12	0.07	0.04
Mineral wool 25 mm thick	0.18	0.24	0.68	0.85	1.00	1.00
Wood stage with void beneath	0.40	0.30	0.20	0.17	0.15	0.10
Water (surface of a pool)	0.01	0.01	0.01	0.02	0.02	0.03
Plaster on brick wall	0.01	0.10	0.06	0.04	0.04	0.03

4.2 Sound Isolation Calculations

When determining the transmission of sound through a partition, the important factors are:

- The transmission loss (TL) properties of the partition
- The area S of the partition exposed to the receiving space
- The volume V of the receiving space
- The reverberation time of the space

The reverberant level in the receiving space can be given by³

$$L_{pr} = L_{ws} + 10 \log S - TL - 10 \log V + 10 \log RT + 14 \text{ dB}$$

where L_{ws} is the sound power level in the source room or outside, and S is the exposed area of the partition to the receiving space.

This equation can be rearranged to determine the required transmission loss of the partition (TL) for a given reverberant background noise limit compatible with the use of the building, as given in Table 1. Chapter 115 also presents an equation to determine the outdoor-to-indoor transmission loss requirements for building facades.

5 ACOUSTIC DESIGN GUIDANCE FOR BUILDING CATEGORIES

This section presents general design guidelines for particular spaces. It should be noted that Chapter 109 deals with noise in offices and open-plan spaces, Chapter 113 deals with noise in mechanical equipment rooms, Chapter 114 deals with noise in single- and multifamily residences, and Chapter 115 deals with noise in commercial and public buildings.

5.1 Performance Spaces (Unamplified)

For unamplified classical music, strong early reflections of instrumental sound is necessary to project to the audience. The musicians themselves also need strong early reflections of sound to gain some feedback to their playing or a sense of ensemble. For this reason,

concert halls are usually designed with highly reflective surfaces located around and close to the stage, angled to provide strong early reflections of sound to the audience. In addition to being hard and reflective, surfaces are often made to be diffusive—hard surfaces with aggressive profiles to scatter sound in various directions rather than providing specular or focused reflections of sound. To prevent discrete late reflections of sound from more distant surfaces such as rear and side walls, which reduce the clarity of instrumental sound, acoustic absorption can also be used.

A modern technique in concert hall design involves the use of acoustic banners that can be unrolled or rolled up to fine-tune the reverberance of the space. The use of movable walls to increase the volume of the space has also been used to adjust the reverberation time of performance spaces. Note that such devices can seriously complicate compliance with the safety regulations in force.

5.2 Amplified Music

For modern amplified music performances in multipurpose venues, there is less reliance on the acoustic characteristics of the building. The ceiling should be absorptive and positioned at a greater height than for unamplified classical performance. Walls around the stage should be a balance of absorptive and diffusive panels to provide some sense of ensemble on stage but also prevent focused reflections of foldback sound toward the performers. Walls around the audience should be absorptive to prevent late reflections of loudspeaker sound from distant surfaces.

5.3 Meeting/Hospitality

If the space is to be used for presentations involving speech, the ceiling should be reflective above and in front of the speaker's head and positioned at low height to obtain useful reflections of sound toward the audience. Ceiling areas away from the speaker, for example, behind the speaker's head, should be absorptive. Side walls near the speaker should be reflective to obtain useful early reflections of sound to the audience and be movable to create a smaller enclosure around the speaker.

A classic scenario is the design of a company boardroom. In this case, the ceiling above the boardroom table should be made hard and reflective to provide early reflections of the speaker's voice to augment

direct sound reaching the listener. The floor and the remaining part of the ceiling should be absorptive to control reverberance in the room. The walls at seated head height should include a band of absorptive material (e.g., fabric panels) to prevent late reflections of sound from the speaker reaching the listener, which would impair the intelligibility of the speech.

5.4 Worship

Modern houses of worship can be used for a wide range of functions in terms of acoustics, including amplified and unamplified speech and music. Even the genre of music played in churches can vary greatly from traditional unamplified choral music to modern amplified rock music. Houses of worship must, therefore, be designed with the same approach as a multipurpose space.

As a consequence, the following acoustic guidelines are provided for houses of worship:

- A reflective ceiling above the stage/pulpit to assist in projection of speech to the congregation
- Sound absorptive treatment to control reverberance to an appropriate mid-frequency reverberation time target for the uses of the space
- Sound absorptive treatment on the rear wall to prevent late reflections of loudspeaker sound
- Appropriately designed sound-isolating constructions (walls and doors) to prevent noise break-out to noise-sensitive receivers

5.5 Industrial/Transport

For transportation and industrial buildings, the aim is to determine the amount and distribution of acoustic absorption likely to be required to control reverberance and to control background noise levels in occupied areas. Speech intelligibility of public address (PA) and emergency public address (EPA) systems is then dependent upon the placement of acoustic treatment and background noise levels.

In the interest of cost efficiency of such buildings, the key is to strike a balance between the PA and EPA system design (type, location, and orientation of the loudspeakers) and the use of acoustic treatment. The strategy is to use the minimum amount of acoustic treatment in optimum locations. For example, priority should be given to placement of acoustic treatment on surfaces likely to produce detrimental reflections of sound from loudspeakers or on curved surfaces likely to focus sound on areas occupied by people.

5.6 Arenas/Stadiums

Partially enclosed arenas and stadiums pose a challenge in terms of acoustic design as, by nature, they include issues related to both fully enclosed spaces and open venues including:

- Aim to provide good speech intelligibility from the PA and EPA systems during sports commentary and emergency message broadcasts.

- Augment the acoustic quality of the sound system if music is required.
- Help provide a feeling of intimacy and excitement for athletes/performers and spectators—this has an important influence on the roof design and materials.
- Ensure that noise from stadium events does not affect surrounding noise-sensitive receivers.
- Ensure that noise from the surrounding area does not disturb athletes/performers inside the stadium/arena.

To provide good speech intelligibility from the sound system in a large volume of space, care is required to ensure that adequate coverage is provided and that, where necessary, provision is made for full-range sound reinforcement loudspeakers (for music) and appropriate delay lines. This is particularly important if the stadium system is to be used in conjunction with a touring system provided by high-profile performers.

Acoustic absorption should be considered in covered areas of the stadium/arena where late reflections of sound are likely to adversely affect speech intelligibility of loudspeaker sound. Such areas include the underside of the roof and rear walls of the venue.

Sources of noise break-out from stadium/arena events include crowd noise, PA announcements, amplified music, and mechanical services plant noise. Positioning of noise sources, such as plant and loudspeakers, away from noise-sensitive receivers is therefore critical. Consideration should be given to the selection of quiet plant and noise mitigation measures (which might include attenuators, screens, and enclosures). Adequate sound isolation performance of the venue facade and roof is also important.

5.7 Critical Spaces

Acoustically critical spaces such as anechoic chambers and broadcast/recording studios require extensive acoustic mitigation to prevent disturbance to the operation of the space. Mitigation methods include structural isolation to prevent vibration and impact noise problems generated by activities and noise sources in surrounding areas. Box-in-box constructions are usually used.

Space planning should be carefully considered to ensure that noisy spaces (e.g., plant rooms) are located far away from the acoustically critical space they are servicing. Building services noise is usually a major consideration for such spaces and represent the baseline noise and vibration sources within these critical spaces. Care must be given to appropriate design of mechanical services fans, prevention of cross talk between adjacent spaces via ductwork, and plant room noise break-out to internal areas.

It should be noted that noise intrusion to broadcast/recording studios is a less significant issue than in the past due to modern close microphone techniques and the use of equalization/high-pass filtering to reduce the impact of low-frequency noise intrusion without significantly affecting the quality of the final output. Determination of appropriate design criteria suitable

for its use is the key to ensuring the successful operation of such a space.

CHAPTER 110

NOISE SOURCES AND PROPAGATION IN DUCTED AIR DISTRIBUTION SYSTEMS

Howard F. Kingsbury
State College, Pennsylvania

1 INTRODUCTION

This chapter deals with the generation, propagation, and control of noise in a ducted air distribution system. First, fan noise control is considered with reference to a simple system, with complications added later. The discussion refers to octave band noise generation and control. Included is discussion of both *natural attenuation*, that is, the noise reduction that occurs due to the transmission of sound through the duct walls, the division of noise due to duct branches, and the effect of duct fittings. Also treated are the effects of porous duct linings and packaged attenuation units (silencers). Consideration is also given to the conversion of sound power levels to sound pressure levels in the room served by the fan system. The methods and effects of varying the air volume delivered by the fan is discussed. Second, turbulent flow noise generation and control in the ducts are covered. The generation and control of *break-out noise*, that is, noise that is radiated through the duct wall, is discussed, as are the differences between round and rectangular duct in the control of this noise. The effects of volume control dampers located near outlets are included. Special consideration is given to roof-top units, where turbulent flow is a common cause of noise generation. Third, noise generation and control in the outlet devices are considered. Both constant-air-volume and variable-air-volume (VAV) types of terminals are

included, including so-called fan-powered terminals. Information on the sound generated by fans is given in Chapter 71.

2 FAN NOISE CONTROL IN DUCTED SYSTEMS

Understanding of noise control in a ducted air distribution system can best be developed by beginning with a simple system and then adding the complications. Figure 1 shows a ducted system reduced to its barest essentials. It is a constant-volume system, with a single fan running at constant speed, enclosed in a plenum, both supplying and returning the air from the room being served. Eliminated from this system are such accessories as heating or cooling coils, filters, and so on. Usually, the most critical part of the system is the room closest to the fan serving that system unless other rooms downstream require lower sound pressure levels.

The recommended noise control procedure is as follows, working in octave bands:

1. Determine the sound power output of the fan(s) that is emitted into the duct system.
2. Determine the so-called natural attenuation of the duct system. While doing so, determine if the sound generated by fittings and takeoffs

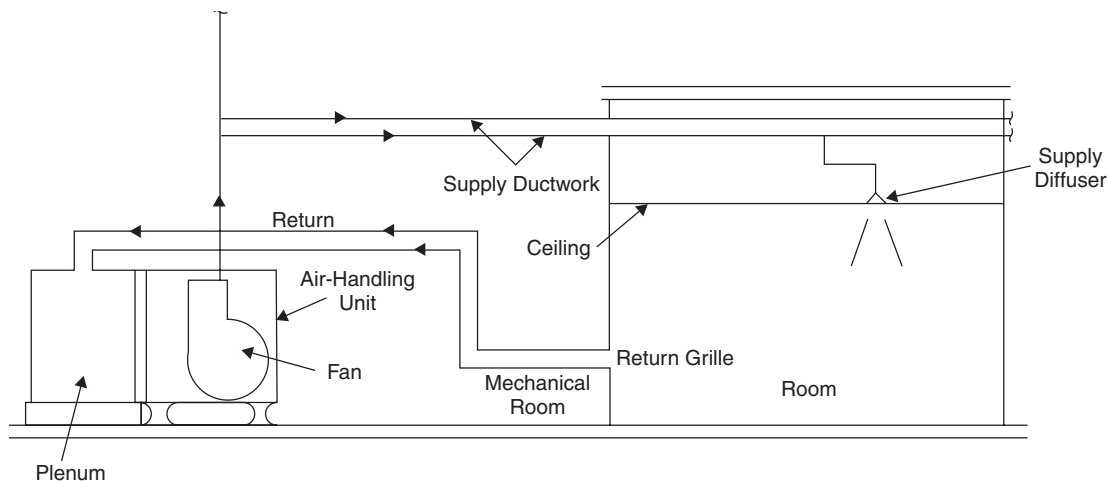

Figure 1 Ducted air distribution system.

Table 1 Attenuation of Unlined Sheet Metal Ducts (dB/unit length) by Octave Band Center Frequency Attenuation (dB/m)

may add to that being transmitted down the duct.

3. Convert from the sound power level at the outlet to the resulting sound pressure level in the space being served (so-called room factor or space effect) and compare it with the chosen sound pressure level criterion for that space.
4. Add any required sound attenuation measures to the system needed to meet the criterion in 3.
5. Determine if sound transmission through the duct wall (break-out noise) may be a problem and, if so, apply proper sound control procedures.
6. Repeat the entire procedure for the return side of the system.

In addition to these considerations of fan noise, note that the final sound pressure level in the room will be a combination of the noise from the fan and noise from the chosen outlet device(s), which will be discussed later.

2.1 Natural Attenuation

The first aspect of noise control in a duct distribution system is the so-called natural attenuation, which has four components. First, some sound is radiated through the duct wall, causing the duct wall to vibrate; this is sensed as a reduction of energy inside the duct (see Table 1). Round and flat oval ducts show less of this effect than rectangular ducts due to their shape. A

Table 2 Division of Sound Power Level at Branch Takeoffs

Ratio ^a	dB Reduction
1.0	0
0.5	3
0.25	6
0.10	10

^a Ratio = branch duct/continuing duct area.

second mechanism is the division of energy between the main duct and the takeoffs. In the absence of specific information to the contrary, it is assumed the energy division is proportional to the ratio of the branch duct area to that of the main duct (see Table 2). A third common loss occurs at the end of the duct, where it enters the room. This is called end-reflection loss (some of the sound energy is reflected back into the duct system) and is most pronounced when there is a sudden transition from the duct to the room. Diffusers reduce this by an unknown amount. However, for diffusers that are round or square (or nearly so), the number in Table 3 will give reasonable results. The effect of high-aspect ratio diffusers, such as slot diffusers, is not known. Finally, a fourth component is the conversion from sound power in the duct system to the sound pressure in the room (the room factor noted above). For most practical rooms, the classical equation (Chapter 2), which assumes both a direct and reverberant field, does

Table 3 Duct End Reflection Loss by Octave Band Center Frequency^a

Mean Duct (mm)	Reflection Loss (dB)				
	63 Hz	125 Hz	250 Hz	500 Hz	1000 Hz
150	18	12	8	4	1
250	14	9	5	1	0
500	9	5	1	0	0
1000	4	1	0	0	0

^a If duct terminates in a diffuser, deduct 6 dB (63 Hz) and 4 dB (125 Hz) for duct sizes under 300 mm, 3 dB (63 Hz) for duct sizes over 300 mm. Do not apply to linear diffusers or diffusers tapped directly into primary ductwork.

Source: From Ref. 1, p. 42.16. Used with permission.

not apply. In a room having an acoustical ceiling and in which the ceiling height is significantly less than either of the horizontal dimensions, the Schultz equation should be used for this conversion.

2.2 Lined Duct Attenuation

In many systems additional attenuation is required. This may be obtained by lining the interior surfaces of the duct with sound-absorbing material or by use of packaged attenuators or both. Duct lining serves two purposes: It is a thermal insulant and a sound absorber. While 13-mm thickness may be sufficient for thermal reasons, for acoustical purposes the thickness should be a minimum of 25 mm, and 50 mm is often desirable. This is due to the minimal low-frequency attenuation provided by thin linings, and it is in the low-frequency region that most duct system noise control problems occur.

The acoustical characteristics of glass fiber duct lining in rectangular ducts have been rather extensively investigated; the same is not true for round ducts, and the data on their attenuation are primarily from manufacturers' determinations. Data for both rectangular and round ducts are shown in Table 4. The data in Table 4 should not be used for ducts with a lightweight metallic foil covering due to the limited transmission loss of such material.

2.3 Lined Rectangular Elbows

Elbows with turning vanes also provide worthwhile attenuation. Round elbows, lined or unlined, provide

relatively little attenuation, in general 5 dB or less. Table 5 provides typical values for rectangular elbows.

2.4 Passive Attenuators or Silencers

These items are available in a variety of sizes, shapes, and lengths. Dissipative silencers commonly contain fiberglass acoustical media; also available are reactive-type silencers that contain no acoustical fill but are composed of a series of tuned resonators that act as the sound-attenuating elements. Commonly available lengths of rectangular silencers are 0.9, 1.5, 2.1, and 3.1 m. The length of most circular cross-sectional silencers is a function of their diameter. In the selection of silencers, three interrelated factors must be considered: (1) insertion loss, (2) pressure drop, and (3) self-generated noise. The primary controlling element is the airflow velocity through the face area of the silencer. Increasing velocity increases both the pressure drop and the self-noise; it reduces the insertion loss slightly. Manufacturers' literature should be consulted for details on these items. A recognized test method for determining these properties is ASTM E477-06a,² which measures the insertion loss by the duct-to-reverberant-room method with and without airflow.

2.5 Active Sound Attenuation

Recent developments in computer technology have led to the development of phase-canceling systems having

application to low-frequency noise in ducted systems. Both random noise and tones are accounted for, with an upper frequency limit of about 400 Hz and insertion losses typically of 20 to 30 dB.

2.6 Attenuation of Noise in Lined Plena

The noise reduction offered by lined fan plena, as shown in Fig. 2, should be taken into account. The following approximate expression, while somewhat dated, may be used to calculate the effects of such a lined plenum³:

$$\text{Attenuation} = 10 \log \left[S_e \left(\frac{\cos \theta}{2\pi d^2} + \frac{1 - \alpha}{\alpha S_w} \right) \right]^{-1} \quad (1)$$

where α is the absorption coefficient of lining at octave band center frequencies, S_e the plenum exit area in square metres, d the slant distance between entrance and exit in metres, S_w the plenum wall area in square metres, and θ the angle of incidence at exit, that is, the angle that d makes with the normal to the exit. The results of this calculation are accurate to within a few decibels for frequencies where the wavelength is much less than the plenum dimensions. It is conservative at low frequencies. For a fuller treatment of the effect of plena, recently published Ref. 4 should be consulted. This covers the experimental determination of the plenum effect for low frequencies as well as high, differing sizes, the effect of different plenum linings, and locations of inlet and outlet. Unhoused fans, mounted on one wall, are being incorporated into plena, where the fan discharges into the plenum, from a bell-shaped inlet. This can result in considerably lower fan sound pressure levels, providing the plenum is large enough and has a sound-absorptive lining.

3 AIR TERMINAL DEVICES

In most ducted systems, a device is placed at the end of the duct to deliver the air to the room. These are most commonly diffusers, grilles, or registers and may contain volume control devices. Since they radiate sound directly into the room, they must be selected to meet the room noise level criterion. For the most part, their noise emissions occur in the octave bands above 250 Hz. Manufacturers' literature should be consulted

for appropriate sound ratings. Care should be taken that the conditions for which the data are presented match the application at hand and any adjustments made as necessary. The noise radiated by a terminal device is dependent not only on the volume and velocity of the airflow through the element but also on the upstream flow conditions. Manufacturer's data are taken under essentially ideal flow conditions; poor flow conditions may add 10 to 15 dB to the catalog data. A variety of upstream airflow conditions and associated additional sound pressure levels are shown in Fig. 3. Frequently, flexible duct is used to connect the terminal device to the branch duct. The length of this flexible duct should be kept as short as possible to avoid additional flow noise, with 1 m being a suggested maximum. Misalignment of the flexible duct can cause increased sound pressure levels, as shown in Fig. 4.

Volume control dampers may be another source of increased noise levels, typically if located close to the outlet. The noise they create is a function of the additional pressure drop they introduce into the system; the additional noise is 20 log of the ratio of the additional pressure drop to that of the diffuser itself. In acoustically critical spaces, volume control dampers should be located well back in the duct system (5 to 10 duct diameters from the outlet), with the lined duct between the damper and the outlet.

3.1 Variable-Air-Volume Systems

For energy conservation reasons, many current air-conditioning systems modulate the airflow to the conditioned space to match the required heating or

Figure 3 Noise effect of poor diffuser flow condition. (From Ref. 1, p. 47.10. Used with permission.)

Figure 2 Diagram of sound-absorbing plenum.

cooling load, as it varies throughout the day and year. These VAV systems have two distinguishing characteristics from the acoustical point of view: (1) a terminal device to modulate the airflow and (2) some method of varying the flow volume from the fan. Such modulation can cause two acoustical problems: (1) loss of privacy when the airflow is at the minimum, due to the lack of diffuser noise, and (2) excess low-frequency noise (rumble), depending on the method of varying the flow from the fan (see Section 3.4).

3.2 Variable-Air-Volume Terminals

In its simplest form, the terminal device consists of an automatically operating damper in a sheet metal box. It is commonly connected directly to the supply duct and with one or more outlets feeding diffusers. Noise is created by the damper as a function of the pressure drop across the damper. This noise can be radiated by two paths: (1) directly through the wall of the unit and (2) downstream through the connected duct(s). This noise is frequently controlled by a section of lined duct between the box and the outlet(s). A more difficult control case is presented when the outlet and VAV terminal are combined. In some situations, the casing-radiated sound must be controlled. In most cases, such terminal units are located over acoustical panel ceilings, which have limited sound transmission loss properties and may contain acoustically transparent areas such as return-air grilles and light fixtures. In general, VAV boxes that handle more than about $0.8 \text{ m}^3/\text{s}$ should not be located over acoustical environments such as offices; they should be located over more noncritical spaces such as corridors, storage areas, or toilet rooms. In some cases, where such acoustically less sensitive spaces are not available and large box sizes must be used, it may be necessary to increase the transmission loss characteristics of the ceiling by incorporating a layer of 12.5-mm gypsum board between the unit and the acoustical ceiling or encasing the box with a 25-mm layer of glass fiber and 12.5-mm gypsum board.

3.3 Fan-Powered VAV Terminals

A special case is a VAV terminal that incorporates a fan to mix the air from the plenum above the ceiling with the primary air. These are called fan-powered terminals (FPTs) and are of two kinds: one in which the fan cycles on and off, as required, and a second in which the fan runs full time. Since the fan in the first goes on and off, the occupants are more aware of the control unit sound. The noise emitted by these units consists of both the noise radiated by the casing and the fan and that through the room air outlet. By reason of the fan contribution to the total direct radiated noise, units handling more than about $0.8 \text{ m}^3/\text{s}$ commonly produce noise levels in the space below corresponding to a noise criteria (NC) rating of 40 or above and hence should not be located over spaces requiring a lower sound level. Some possible noise control measures for these units include, in addition to moving them to more remote locations, keeping them

at least 2 m from any open return grilles in the ceiling, installing sound attenuators if offered as an option by the manufacturer, or field fabricating lined elbows for installation on the induced air opening of the FPT. Consult manufacturers' literature for appropriate information on the noise levels produced by these units and how to determine the noise levels in the occupied space served by them. Data on these units are taken in accordance with the Air-Conditioning & Refrigerating Institute (ARI) Standard 880–98.⁵ See Ref. 1 for estimation of the sound pressure level in the occupied space.

3.4 Fan Volume Control

As the airflow volume through the terminals varies to meet the required heating or cooling load, the volume of air produced by the fan must also vary. There are three basic methods of doing so: (1) use of inlet vanes on the fan, (2) motor speed controls, and (3) varying the pitch of the fan blades.

Inlet vanes are positioned at the inlet to the fan scroll and close down to reduce airflow. They add resistance to the system and, depending on the fan type, may cause significant additional low-frequency fan sound, which must be dealt with further downstream. Since resistance to flow is added, there is also energy usage inefficiency when the vanes are in their partially open position.

Variable-speed controls reduce the speed of the fan and thus the volume flow; they also reduce the fan noise generation. Variable-speed controls have a significant energy savings over inlet vanes; this should be taken into account in the selection process.

Variable-pitch blades are available for some axial-flow fans; this also results in quieter operation at reduced flow.

4 SOUND TRANSMISSION THROUGH DUCT WALLS

Sound radiated through duct walls may be a problem if not sufficiently attenuated before the duct passes over or through occupied space. This is most frequently a problem close to the fan room, where the noise in the duct may be composed of both that from the fan and that aerodynamically generated due to poor flow conditions. Typically, this noise is concentrated in the octave bands below 250 Hz and may extend down through the 31.5-Hz band. It is commonly called *break-out noise*, and its level is dependent on the noise level within the duct, the duct cross section, and the length of the duct in or over the occupied space. The transmission loss characteristics of rectangular, flat oval, and round ducts have been determined; representative values for round and rectangular ducts are shown in Table 6. The transmission loss of rectangular ducts does not vary significantly as a function of duct size or construction; the transmission loss of round ducts does vary as a function of the duct diameter and values for several typical diameters are included. Note that at low frequencies the transmission loss of round ducts is markedly higher than for rectangular ones. Using round ducts is an excellent

Table 6 Transmission Loss_{out} for Rectangular and Round Duct by Octave Band Center Frequency (Hz)

350	>48	>53	55	33	34	35
650	>48	>53	36	32	32	28
800	>48	42	38	25	26	24

Source: Ref. 1, p. 42.23. Used with permission.

method of controlling low-frequency break-out noise. Since the noise is better contained, additional duct system attenuation may be needed downstream for appropriate control of room sound pressure levels. The transmission loss of flat oval duct is intermediate between rectangular and round duct, but due to the relatively large flat surfaces, it tends to follow the same characteristics as that of rectangular duct, that is, lower values at low frequencies.

5 TURBULENT AIRFLOW NOISE CONTROL

Although fans are usually the major source of noise in a duct system, aerodynamic noise may be generated at elbows, turns, takeoffs, silencers, and other duct elements. The generated noise levels depend on the element geometry as well as the airflow velocity. Since the intensity of flow-generated sound is proportional to between the fifth and sixth power of the local velocity in the duct, the best methods of control are to (1) keep the duct velocities as low as possible and (2) avoid closely spaced elements (turns, takeoffs) or abrupt changes in duct area that can contribute to turbulent flow. In general, if the flow velocities are below about 10 m/s and elements can be separated by about three

to five duct diameters, most aerodynamically induced noise control problems are minimized.

6 ROOFTOP UNITS

Rooftop units (packaged, factory-assembled units containing fans and associated heating and cooling equipment) pose important noise control problems. They are frequently mounted on curbs supported by lightweight roof structure directly above occupied space. Because of their proximity to the building interior, they should be located over acoustically noncritical spaces. The primary noise paths that need consideration, as shown in Fig. 5, are¹ (1) the casing-radiated noise, (2) the supply and return-air ducts, and (3) structure-borne noise.

6.1 Casing-Radiated Noise

This noise is best controlled by making certain the roof structure inside the curb has adequate mass to block the sound being radiated by the fan casing and compressor, if included. This construction may consist of concrete or multiple layers of gypsum board. Sealing around the perimeter of the curb and around the supply and return duct penetrations is important. The supply and

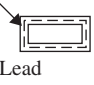

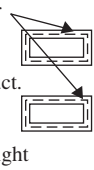

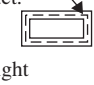

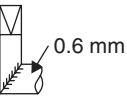

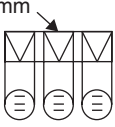

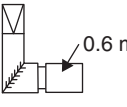

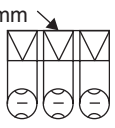

Figure 5 Noise paths in typical rooftop installations. (From Ref. 1, p. 47.6. Used with permission.)

Table 7 Duct Break-out Insertion Loss: Potential Low-Frequency Improvement over Bare Duct Elbow

Source: Ref. 1, p. 47.8. Used with permission.

return ducts are commonly directly above the ceiling of the occupied space, and often there is insufficient space for easy application of adequate noise control measures. On the supply side, low-frequency break-out noise is a common problem. Control methods consist of proper configuration of the fan outlet and ducts. A common problem is the duct elbow between the fan outlet and the horizontal duct above the ceiling. Round elbows and round duct are a very important way of controlling this noise. See Table 7.

6.2 Structure-Borne Noise

This noise is controlled by proper vibration isolation. Internal isolation of fans in units without compressor/condenser units will usually be sufficient if the isolators have adequate deflection; steel springs of 50 to 75 mm deflection are usually required. Several manufacturers can supply curbs with high deflection springs for such isolation.

An alternate noise control technique is to raise the unit above the roof on a structure (commonly called dunnage). In this configuration, the ducts can be run above the roof before entering the building, creating

the opportunity to include noise control measures before the ducts enter the building; casing-radiated noise through the bottom of the unit is also less difficult. If the unit contains compressor/condenser units, it is usually necessary to isolate the entire unit. Vibration transfer to a lightweight roof is avoided since the dunnage is usually supported from heavier roof-supporting structures.

1 INTRODUCTION

The interaction between the turbulent airflow and discontinuities in low-speed flow ducts, such as in ventilation systems, can result in the generation of noise as eddies are shed from duct irregularities or even the rough sides of the airways. In free space these turbulent eddies are relatively harmless as they are inefficient noise generators at the velocities encountered in ventilation systems. Efficient generation of noise occurs when the turbulence is shed from the object or discontinuity or when it impinges subsequently on an obstruction, and the corresponding velocity variations are converted into pressure fluctuations. Airflow noise increases as approximately the sixth power of flow velocity and is generally broadband. The spectrum of the noise produced will depend on the size of the obstacle or discontinuity and the maximum velocity. For typical fittings and flow velocities, the overall regenerated power level is likely to be in the region of 50 to 70 dB, but the levels vary with frequency. At considerable distances from the fan, airflow-generated noise from duct fittings can become the major noise problem. If the fittings are located near terminal devices, there may not be enough duct length available between the duct fitting and terminal device to provide sufficient attenuation of the flow-generated noise.

2 SOURCES OF NOISE IN FLOW DUCTS

Although extensive research on flow-generated noise has been carried out over the past 40 years, the emphasis has largely been on jet engine noise (see Chapter 9). The airflow speeds involved in this situation are generally close to the speed of sound and not applicable to the situation of ventilation systems where velocities between 10 and 30 ms⁻¹ are common. Relatively little is known about the situation of noise produced by turbulent flow in ventilation systems, which is complicated by the presence of resonances and flow instabilities.

In ventilation systems, turbulent mixing can occur in the absence of solid surfaces, for example, induction

airstream mixing and boundary layer turbulence. When the air leaves the duct, it enters a region of zero-flow velocity. The high-velocity gradients that exist at the interface of the moving and stationary media produce shear forces in the fluids, which generate turbulent mixing and noise. The noise sources are distributed spatially along and across the regions of mixing. Lighthill has proposed that a quadrupole represents a model of the acoustic source that dominates high-speed subsonic, turbulent air jets.^{1,2}

Curle extended Lighthill's general theory of aerodynamic sound by incorporating the effect of solid boundaries upon the sound field.³ These effects include reflection and diffraction of the sound waves at the solid boundaries and a resultant dipole field at the solid boundaries. When turbulent flow interacts with a solid surface, or when turbulence in the form of a wake is generated by a solid surface, changes occur in the momentum field around the spoiler that are time-dependent, require fluctuating forces, and these must in general exist on the solid surface. Any such forces may be resolved into *lift* and *drag* components, and the sound generated is represented by an acoustic dipole, the axis of which is aligned with that of the fluctuating force. If the dipole source distribution is random, the sound spectrum is of a broadband nature. A well-ordered distribution results in a discrete sound spectrum.

Gordon has demonstrated, by means of a simple yet elegant experiment, that the wideband noise resulting from the interaction of airflow with an in-duct flow spoiler increases as the sixth power of flow velocity.^{4,5} This is consistent with the generally accepted view that most of the sound generation mechanisms in ventilation systems can be represented by the dipole character.

The analysis of noise generated by flow spoilers usually assumes that the spoilers are small compared to the wavelength of sound at the frequency in question to ensure that the flow field in the neighborhood of the spoiler may be treated as incompressible. Davies and Ffowcs-Williams have noted that when a sound source is confined within an infinitely long duct of diameter

small in comparison to a wavelength, the character of the problem changes from three dimensional to one dimensional.⁶ This change affects both the acoustic impedance of the surroundings and the amount of sound power radiated by the source. At low frequencies, the dipole sources, when confined in a small-diameter duct, would have sound power outputs increasing as U^4 rather than the familiar U^6 characteristics of these sources in an infinite fluid. As the frequency of the sound source increases, the sound power radiated by the source in the duct approaches that in the free field.

3 APPROACHES TO THE PREDICTION OF AIRFLOW-GENERATED NOISE IN VENTILATION SYSTEMS

Empirical formulas for predicting the sound power level generated by in-duct components are generally based upon the assumption of a sixth-power law dependence of sound power on air velocity and involve an equation of the following form:

$$L_W = C + 10 \log A + 60 \log(U_c) \quad (1)$$

where L_W is the airflow-generated noise power level (dB), C is a constant, which varies with the fitting, A is the minimum flow area of the fitting (m^2), and U_c is the maximum flow velocity in the fitting (ms^{-1}). In Eq. (1) the logarithm of the velocity is multiplied by 60, which is the result of assuming a U^6 dependence of sound power on flow velocity. Equation (1) illustrates the importance of limiting the velocity since a doubling of velocity results in an 18-dB increase in regenerated sound power.

The intensity of the noise generated from the airflow will be determined primarily by the magnitude of the velocity increase created by the obstruction and so forth. The spectrum of the noise produced will depend on the size of the obstacle or discontinuity and on the maximum velocity. In general, the spectrum is a function of a representative dimension of the obstruction or discontinuity d , and the maximum (or constricted) flow rate around the obstacle or through the discontinuity U_c .

Flow noise data can normally be "nondimensionalized" by expressing spectral data as a function of a Strouhal number, St , given by

$$St = f_c d / U_c \quad (2)$$

where f_c is the octave band center frequency.

The calculation of the Strouhal number is, in general, the starting point for predicting flow-generated noise. The ventilation system designer usually tries to predict flow-generated noise using procedures laid down in such publications as the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) or the UK Chartered Institution of Building Services Engineers (CIBSE) guides.^{7,8} The information contained in these publications has been drawn from the published work of a number of different investigators who worked on a limited range of in-duct components and a limited range of duct sizes.^{9,10}

Application of their results to systems often having very different configurations from those on which the original measurements were made can produce dubious results. Attempts have been made to use the limited available data to develop more generalized prediction methods for various types of duct component.

4 PREDICTION OF AIRFLOW GENERATED NOISE IN VENTILATION SYSTEMS DUE TO IN-DUCT ELEMENTS

For in-duct elements such as bends, transition pieces, damper, and the like, the results of recent research have led to a prediction method based upon pressure loss characteristics. The effect of a discontinuity in a duct carrying airflow is to generate turbulence, some of which is converted into sound energy. The power required to generate the turbulence in the vicinity of the discontinuity is supplied by the system fan, and the work done by the fan in the region of a discontinuity is manifested as a loss of static pressure across the discontinuity. The larger the discontinuity, the greater is the pressure loss and the greater is the sound power radiated. The pressure loss characteristics of an in-duct element are usually expressed in terms of a pressure loss coefficient, C_L , given by

$$C_L = \Delta P / 0.5 \rho_0 U^2 \quad (3)$$

where ΔP = static pressure loss due to the component

U = velocity of air in unobstructed region of the duct

ρ_0 = density of air

The pressure-based prediction method is based upon a theory originally proposed by Nelson and Morfey.¹¹ The underlying assumption of this theory is that the sound power radiated by an in-duct spoiler is related to the total fluctuating drag force acting on the spoiler, which is a function of the turbulence intensity in the region of the spoiler. Since they were unable to determine the actual spectrum of the turbulence intensity in the vicinity of the spoiler, Nelson and Morfey made the further assumption that the fluctuating drag force is in direct proportion to the steady drag force. This assumption had originally been made by Gordon^{4,5} and was later experimentally verified by Heller and Widnall.¹²

Nelson and Morfey collapsed their experimental data into a generalized spectrum to form the basis of a predictive technique by the empirical evaluation of the constant of proportionality between the fluctuating and steady drag forces as a function of Strouhal number. However, their curves were obtained from measurements made on simple strip spoilers for which the necessary parameters for determining the Strouhal number, a representative dimension and open-area ratio (which determined the constriction velocity in the region of the spoiler), could be established by simple inspection. In work on airflow-generated noise in ducts arising from the presence of inclined dampers and orifice plates, Oldham and Ukpoho extended the work

of Nelson and Morfey to other spoiler configurations.¹³ They first rewrote the Nelson and Morfey equations in terms of the pressure loss coefficient, which is a parameter more commonly used in ventilation system design than the drag coefficient employed by Nelson and Morfey. They then proposed the use of simple empirical methods based upon measurement of the pressure loss coefficient to determine the open-area ratio and the characteristic dimension for more complex spoilers. The equations obtained resulting from these modifications are shown below.

For $f_c < f_0$,

$$120 + 20 \log_{10} K(\text{St}) \\ = SWL_D - 10 \log_{10} [\rho_0 A \sigma^4 C_L^2 U_C^4 / 16 c_0] \quad (4)$$

For $f_c > f_0$,

$$120 + 20 \log_{10} K(\text{St}) \\ = SWL_D - 10 \log_{10} [\rho_0 \pi A^2 (\text{St})^2 \sigma^4 C_L^2 U_C^6 / 24 c_0^3 d^2] \\ - 10 \log_{10} [1 + (3\pi c_0 / 4 \omega_c)(a + b) / A] \quad (5)$$

where $K(\text{St})$ = Strouhal number dependent constant

SWL_D = in-duct sound power level

f_c = center frequency of the band of frequencies under consideration

ω_c = angular center frequency

f_0 = cut-on frequency of the duct

c_0 = speed of sound in air

A = cross-sectional area of duct

a = duct height

b = duct width

The open area ratio is given by

$$\sigma = \frac{C_L^{1/2} - 1}{C_L - 1} \quad (6)$$

The maximum effective (constriction) velocity is given by

$$U_C = \frac{U}{\sigma} \quad (7)$$

The characteristic dimension is given by

$$d = \frac{A(1 - \sigma)}{b} \quad (8)$$

The Strouhal number is given by:

$$\text{St} = \frac{f_c d}{U_C} \quad (9)$$

Note there are different expressions for noise regeneration below and above the duct cut-on frequency, which is the frequency above which complex acoustic modes are propagated in the duct.

Waddington and Oldham have recently applied Eqs. (4) to (9) to data measured on a number of in-duct

Figure 1 Collapse of measured sound power level data as a function of Strouhal Number for mitred bends without vanes: (x) 0.4-m diameter, (o) 0.6-m diameter.

elements.¹⁴ Figure 1 shows the collapse of measured data on the basis of the above equations for a range of component sizes and duct air velocities. It can be seen that individual spectra corresponding to different air velocities and component sizes collapse onto one single spectrum, and the best-fit curve through this data then forms the basis of a predictive design curve for this type of component. From knowledge of the pressure loss coefficient, duct dimensions, and air velocity one can calculate the sound power level for any chosen octave band center frequency. It is necessary to first obtain values for the clear-area ratio and the characteristic dimension d . As shown above, the clear-area ratio can be approximated by a simple function of the pressure loss coefficient, which is plotted in Fig. 2.

The procedure for determining the regenerated noise level for a given one-third octave band frequency is thus as follows:

1. Determine the clear-area ratio σ , from Eq. (6) or Fig. 2.

Figure 2 Clear-area ratio as a function of pressure loss coefficient.

2. Calculate the constriction velocity U_c from Eq. (7).
3. Calculate the representative dimension d from Eq. (8).
4. Calculate the Strouhal number (St) corresponding to the chosen one-third octave band center frequency f_c , d and U_c from Eq. (9).
5. Read off appropriate value of $20 \log [K(\text{St})]$ from the best-fit curve in Fig. 1.
6. Insert values in Eq. (4) or Eq. (5) depending on whether the one-third octave band frequency f_c is below or above duct higher mode cut-on f_0 .

5 PREDICTION OF AIRFLOW-GENERATED NOISE IN VENTILATION SYSTEMS AT TERMINAL DEVICES

As there is no opportunity to attenuate energy produced by terminal units such as grilles, diffusers, and induction units, before it reaches the room, flow noise generation at terminal units is of particular importance. Two main types of diffuser can be identified:

1. Circular ceiling diffusers supplied through circular ductwork with a neck area of A_N with or without plenum boxes.
2. Linear and rectangular grilles, registers, or slots fed from plenum boxes and having a free discharge area A_F .

For both types the radiated sound power level is given by the general equation:

$$L_w = \text{Constant} + 57 \log Q - 47 \log A \quad \text{dB} \quad (10)$$

where Q is the volume flow rate (m^3s^{-1}) and A is the area (m^2).

The form of this expression will apply for the overall total radiated sound power level or to the octave bands of the noise spectrum; however, the constant term will vary and can be determined experimentally. It can be seen that the radiated sound power level is very sensitive to changes of flow rate or grille area.

A typical value for the total radiated sound power level is given by¹⁵

$$L_{w\text{total}} = 32 + 57 \log Q - 47 \log A_F \quad \text{dB} \quad (11)$$

A similar expression relates the total radiated sound power level to neck flow rate:

$$L_{w\text{total}} = 32 + 60 \log V_N + 13 \log A_N \quad \text{dB} \quad (12)$$

where V_N is the neck (or maximum) flow velocity in metres/second.

Figure 3 illustrates general spectral distribution for circular diffusers, which can be applied directly to the overall sound power level. The Strouhal number is given by the product of frequency and neck diameter divided by the neck flow velocity. Octave band levels at frequencies higher and lower than the peak frequency can also be obtained approximately

Figure 3 Generalized spectrum for diffuser.

by deducting 3 dB/octave at lower frequencies and deducting 5 dB/octave at higher frequencies.

When the duty of a diffuser is specified by the volume flow rate Q and the pressure drop ΔP , the general equation becomes

$$L_{w\text{total}} = \text{Constant} + 10 \log Q + 26 \log \Delta P \quad \text{dB} \quad (13)$$

where ΔP is the grille pressure drop in pascals. An alternative approach to the prediction of diffuser noise can be found in Berarek and Ver¹⁶ and *Sound and Vibration Design and Analysis*.¹⁷

Ceiling diffusers designed to deflect the air horizontally, known as having a wide throw, will exhibit a greater pressure loss and generate more noise than those with a small or no throw, as illustrated in Fig. 4.

A control damper added to a grille or diffuser will increase the flow noise generated by a diffuser. A vortex shedding noise component will arise from the damper blades themselves, but more significantly there will also be the impact of the damper blade turbulence wake upon the grille or diffuser vanes. Manufacturers of grilles

Figure 4 The effect of diffuser throw on sound power generated.

and diffusers usually supply data for the sound power level produced for their grille/damper assemblies, as a function of face velocity, volume flow rate or pressure drop across the unit. In the absence of such data an increase in the above-estimated sound power level of 5 dB can be assumed in each octave band for the addition of an integral damper vane set fully open. It can further be assumed that, for subsequent flow adjustment resulting in an increase in pressure drop across the damper, the overall sound power level will increase approximately according to the following equation:

$$\Delta L_{w\text{total}} = 33 \log(\Delta P / \Delta P_0) \text{ dB} \quad (14)$$

where ΔP is the static pressure drop across the unit and ΔP_0 is the pressure drop for the same volume flow rate with damper vanes fully open.

6 DESIGNING FOR LOW FLOW-GENERATED NOISE

There are a number of simple principles for duct design that should be followed in order to avoid turbulence and the associated pressure loss and noise.¹⁸ Flow-generated noise in duct fittings can be reduced by choosing geometries that minimize the generation of vortices and the interaction of the vortices with sharp edges. Some obstructions, such as dampers, are necessary, but multiple dampers are preferred to single dampers in a noise-sensitive system. Dampers should be fitted at least 1.5 to 2.0 m back from a duct termination in order to reduce damper noise escaping into occupied space.

The noise generated at bends can be reduced by the use of circular bends rather than mitered bends. Splitters or turning vanes can also be employed to enhance the airflow at bends. In critical situations, narrow chord and large radius bends are preferable.

Cross-sectional area changes where flow separation occurs should be avoided. The transition angle should be less than 10° to minimize the risk of flow detachment. In critical situations, if the available transition length is insufficient to obtain less than a 10° transition angle, a perforated plate can be employed to diffuse the flow evenly into the larger duct. The high-frequency noise generated by the perforated plate can be easily attenuated by duct lining downstream of the area change.

Flow-generated noise at branchings and takeoffs can be reduced by using duct fittings that provide a smooth flow and by avoiding a change of velocity pressure, especially the reduction of the velocity pressure, which is usually accompanied by flow separation. Cross and tee junctions where the volume flow in one branch is substantially smaller than the volume flow in the other branches should be avoided. A branch takeoff should be more than five duct diameters downstream of the main junction so that the turbulence generated in the main junction decays before it reaches the downstream branching.

It should be noted that there are other aspects of flow-generated noise that have not been covered in this brief chapter. Attenuators constitute a possible source of in-duct turbulence such that they not only reduce noise generated elsewhere in the system but

can also generate significant self-noise. Attenuator manufacturers, therefore, typically provide both static (no flow) and dynamic (with airflow) insertion loss data. It is also possible for the turbulent flow downstream of a discontinuity to excite the relatively thin walls of a duct into vibration and thus cause significant noise break out.

CHAPTER 112

NOISE CONTROL FOR MECHANICAL AND VENTILATION SYSTEMS

Reginald H. Keith
Hoover & Keith, Inc.
Houston, Texas

1 INTRODUCTION

To evaluate the acoustical impact of mechanical equipment rooms, detailed knowledge of the acoustical emission levels of the mechanical equipment is required. The best source for these data is the equipment manufacture. However, in the initial design the specific manufacturer and equipment model may not be known. The information given in this chapter is suggested for initial design uses.

2 SOUND PRESSURE AND SOUND POWER LEVELS FOR TYPICAL EQUIPMENT

These data are presented in the form of octave band sound power levels (re 10^{-12} W) or normalized octave band sound pressure levels. The normalized octave band sound pressure level data are representative of a distance at 1 m and a room constant of 75 m².

2.1 Chillers^{1,2}

Chillers are used to provide cooling water for air-conditioning systems. The three principal types are (1) packaged chillers with reciprocating compressors, (2) packaged chillers with rotary-screw compressors, and (3) packaged chillers with centrifugal compressors. In addition, absorption machines, which are heat-operated refrigeration machines, are sometimes used to provide cooling water. Specific considerations for each classification are as follows:

Packaged Chillers with Reciprocating Compressors The overall sound power level can be expressed by

$$L_W = 82 + 8.5 \log(CC) \quad (1)$$

where CC is the rated cooling capacity in kilowatts. The specific octave band sound power levels are shown in Table 1.

Packaged Chillers with Rotary-Screw Compressors The octave band sound power levels representing near-maximum noise levels for the size range of 350 to 1000 kW cooling capacity, operating at or near 3600 rpm are shown in Table 2.

Packaged Chillers with Centrifugal Compressors Packaged chillers can be divided into three groups. A description of each group is given together with an equation to compute the overall sound power level (where CC is the cooling capacity in kilowatts). The values in Table 3 can be subtracted from the

overall sound power level to obtain the octave band sound power level.

Group 1 is for internally geared, hermetically sealed centrifugal compressors rated at or under 3500 kW. The overall sound power level for the compressors in this group is given by

$$L_W = 78 + 9 \log(CC) \quad (2)$$

Group 2 is for direct-drive, hermetic compressors rated at or under 3500 kW. The overall sound power level for the compressors in this group is given by

$$L_W = 60 + 14 \log(CC) \quad (3)$$

^aGroup 1: Internally geared hermetic, or if drive arrangement is not known, at and under 3500 kW.

^bGroup 2: Direct-drive hermetic, at and under 3500 kW.

^cGroup 3: All hermetic above 1000 tons (3500 kW).

Group 3 is for all hermetic compressors rated at or above 3500 kW. The overall sound power level for the compressors in this group is given by

$$L_W = 90 + 6 \log(CC) \quad (4)$$

Absorption Machines The sound of absorption machines is generally masked by other noises in a mechanical equipment room. The machine usually includes one or two small pumps; steam flow noise or steam valve noise may also be present. The overall sound power level is normally less than 100 dB and the A-weighted sound power level is less than 96 dB.

Built-up Refrigeration Machines The sound of packaged chillers, as presented in the preceding paragraphs, includes the sound of both the compressor and the drive unit. If a refrigeration system is built of separate pieces, then the noise level estimate should include the noise of each component making up the assembly. Compressor sound power levels should be taken from the packaged chiller data. Sound power level data for the drive units (motors, gears, steam turbines) should be taken from the appropriate tables in this chapter or obtained from the manufacturers.

2.2 Boilers¹

The wide variety of blower assemblies, air and fuel inlet arrangements, burners, and combustion chambers provides such variability in the noise data that it is impossible to correlate noise with heating capacity. Sound power levels at the normalized 0.9-m distance may be as high for the smallest as for the largest units. The estimated sound power levels given in Table 4 are believed applicable for all boilers in the size range of 50 to 2000 boiler horsepower (1 bhp = 33,500 Btu/h or 9818 W). These sound power levels apply to the front of the boiler. Thus, when other distances are of concern, the distance should always be taken from the front surface of the boiler. Sound power levels are lower off the side and rear of the typical boiler.

Table 4 Sound Power Levels for Boilers

2.3 Cooling Towers^{1,2}

Four general types of cooling towers are sketched in Fig. 1: centrifugal-fan flow-through type, axial-flow blow-through type (with the fan or fans located on a side wall), induced-draft propeller type, and “underflow” forced-draft propeller type (with the fan located under the assembly).

Sound Power Level of Propeller-Type Cooling Towers The approximate overall sound power levels of propeller-type cooling towers are given by

$$L_W = 100 + 8 \log(\text{fan kW})$$

for overall L_W , under 75 kW (5)

$$L_W = 96 + 10 \log(\text{fan kW})$$

for overall L_W , over 75 kW (6)

where fan kilowatt is the nameplate power rating of the motor that drives the fan. Octave band sound power levels can be obtained by subtracting the values of Table 5 from the overall L_W obtained by Eq. (5) or (6).

Table 5 Frequency Adjustments (in dB) for Propeller-Type Cooling Towers

Figure 1 Principal types of cooling towers. (a) Centrifugal-fin blow-through type, (b) axial-flow blow-through type, (c) induced-draft propeller type, and (d) forced-draft propeller-type underflow.

Sound Power Level of Centrifugal-Fan Cooling Towers The approximate overall sound power levels of centrifugal-fan cooling towers are given by

$$L_W = 85 + 11 \log(\text{fan kW})$$

for overall L_W , under 60 kW (7)

$$L_W = 93 + 7 \log(\text{fan kW})$$

for overall L_W , over 60 kW (8)

where fan kilowatt is the nameplate power rating of the motor that drives the fan. When more than one fan or cooling tower is used, the fan power rating should be the total motor drive rating of all fans or towers. Octave band sound power levels can be obtained by subtracting the values of Table 6 from the overall L_W obtained by Eq. (7) or (8).

Directionality of Cooling Towers Cooling towers usually radiate different amounts of sound in different directions, and the directional adjustments of Table 7 should be made to the octave band sound power levels (PWLs). These corrections apply to the five principal directions from a cooling tower, that is, in a direction perpendicular to each of the four sides and to the top of the tower.

Noise Reduction with Reduced Fan Speed When it is practical to do so, the cooling tower

Table 6 Frequency Adjustments (in dB) for Centrifugal-Fan Cooling Towers

fan can be reduced to half speed in order to reduce noise. Half speed produces approximately two-thirds cooling capacity and approximately 8- to 10-dB noise reduction in the octave bands that contain most of the fan-induced noise. For half-speed operation, the octave band L_p or L_W of full-speed cooling tower noise may be reduced by the following amounts, where f_B is the blade passage frequency and is calculated from the relation $f_B = \text{number of fan blades} \times \text{shaft rpm}/60$:

Table 7 Corrections to Average SPLs for Directional Effects of Cooling Towers

$\frac{1}{8} f_B$	3 dB
$\frac{1}{4} f_B$	6 dB
$\frac{1}{2} f_B$	9 dB
$1 f_B$	9 dB
$2 f_B$	9 dB
$4 f_B$	6 dB
$8 f_B$	3 dB

If the blade passage frequency is not known, it may be assumed to fall in the 63-Hz band for propeller-type cooling towers and in the 250-Hz band for centrifugal cooling towers. Waterfall noise usually dominates in the upper octave bands, and it would not change significantly with reduced fan speed.

Closed Confined Locations Most of the preceding discussion assumes that cooling towers will be used in outdoor locations. If they are located inside enclosed mechanical equipment rooms or within courts formed by several solid walls, the sound patterns will be distorted. In such instances, the L_W of the tower (or appropriate portions of the total L_W) can be placed in that setting, and the enclosed or partially enclosed space can be likened to a room having certain estimated amounts of reflecting and absorbing surfaces.

2.4 Pumps^{1,2}

The overall normalized sound pressure levels for pumps are given in Table 8 and are representative of most pumps encountered in commercial situations. The pump power rating is taken as the nameplate power of the drive motor. Octave band sound pressure levels are obtained by subtracting the values of Table 9 from the overall sound pressure level of

Table 8 Overall Sound Pressure Levels in dB at 1-m Distance for Pumps

Speed Range (rpm)	Drive Motor Nameplate Power	
	Under 75 kW	Above 75 kW
3000–3600	71 + 10 log hp	85 + 3 log hp
1600–1800	74 + 10 log hp	88 + 3 log hp
1000–1500	69 + 10 log hp	83 + 3 log hp
450–900	67 + 10 log hp	81 + 3 log hp

Table 8. Pumps intended for high-pressure operation have small clearances between the blade tips and the cutoff edge and, as a result, may have higher noise peaks in the octave bands containing the impeller blade passage frequency and its first harmonic. These would usually fall in the 1000- and 2000-Hz octave bands.

2.5 Fans^{3,4}

Manufacturers often furnish in-duct sound power level data of their fans on request. However, in early designs the specific model or manufacturer is not known. In these cases, the octave band sound power of a fan can be estimated by^{3,4}

$$L_W = K_W + 10 \log Q + 20 \log P + \text{BFI} + C - 45 \quad (9)$$

where L_W is the total in-duct sound power level of the fan (inlet and outlet), K_W is the specific sound power level for the particular fan design (Table 10), Q is the volume flow rate in liters per second (L/s), and P is the static pressure produced by the fan in pascals (Pa). The blade frequency increment (BFI) is added to the octave band containing the blade passage frequency (i.e., rotational rate of the fan in cycles per second times the number of fan blades). The estimate given by this method assumes ideal inlet and outlet flow conditions and operation of the fan at its peak design condition. The sound emission level is quite critical to these conditions and increases significantly for deviations from ideal. Based on studies of noise and operational data from several fan manufacturers, Warren Blazier⁴ suggests an additional correction to Eq. (9): Add 1 dB to the fan noise for each 3% efficiency below 95% of peak static efficiency for the particular fan operation. It is suggested that if the operating static efficiency is not known, 5 dB be added to the levels obtained from

Eq. (9). The operating static efficiency of a fan may be calculated by

$$\text{Static efficiency} = \frac{Q \times P}{1002 \times \text{BkW}} \quad (10)$$

where Q is air volume in liters per second, P is total static pressure in kilopascals, and BkW is the brake power in kilowatts. The ratio of calculated static efficiency to peak efficiency determines the correction factor C . For cursory design the maximum peak efficiency can be taken as 65% for centrifugal fans with forward curved blades, 80% for centrifugal fans with backward inclined blades, and 70% for vane axial fans.

The fan housing and its nearby connected ductwork radiate fan noise into the fan room. Because of the number of variables involved, there exists no simple analysis procedure for estimating the L_W of the noise radiated by the housing and ductwork. However, Table 11 offers a method to estimate this type of noise. These are simply deductions, in decibels, from the induct fan sound power levels.

2.6 Air Compressors¹

The normalized sound pressure levels for air compressors commonly found in commercial buildings are given in Table 12.

2.7 Emergency Generators¹

Emergency generators are typically driven by reciprocating engines or small gas turbines. As a general rule,

the sound pressure level of the generator is not significant with respect to the driver. Typically, each engine type has three sound sources of interest: the engine casing, the air inlet, and the engine exhaust.

Reciprocating Engines The overall L_W radiated by the casing of a natural-gas or diesel reciprocating engine is given by

$$L_W = 93 + 10 \log(\text{rated kW}) + A + B + C + D \quad (11)$$

where L_W is the overall sound power level (dB), “rated kW” is the engine manufacturer’s continuous full-load rating for the engine, and A , B , C , and D are correction terms given in Table 13.

Octave band sound power levels for the casing can be obtained by subtracting Table 14 values from the overall L_W given by Eq. (11) together with any the modifications of Table 13.

Most large engines have turbochargers at their inlet to provide pressurized air into the engine for increased

performance. Turbine configuration and noise output can vary appreciably, but an approximation of the L_W for the turbocharged inlet is given by

$$L_W = 95 + 5 \log(\text{rated kW}) - \frac{L}{1.8} \quad (12)$$

where L_W and “rated kW” are as previously defined, and L is the length, in metres, of a ducted inlet to the turbocharger. The octave band adjustments given in Table 15 are subtracted from the overall L_W of Eq. (12) to obtain the octave band sound power levels of turbocharged inlet noise.

The sound power level of the noise radiated from the unmuffled exhaust of an engine is given by

$$L_W = 120 + 10 \log(\text{rated kW}) - T - \frac{L}{1.2} \quad (13)$$

where T is the turbocharger correction term ($T = 0$ dB for an engine without a turbocharger and $T = 6$ dB for an engine with a turbocharger), and L is the length, in metres, of the exhaust pipe. The octave band sound power levels of unmuffled exhaust noise are obtained by subtracting the values of Table 16 from the overall

L_W derived from Eq. (13). If the engine is equipped with an exhaust muffler, the final noise radiated from the end of the tailpipe is the L_W of the unmuffled exhaust minus the insertion loss of the muffler.

Small Gas Turbine As with reciprocating engines, the three principal sound sources of turbine engines are the engine casing, the air inlet, and the exhaust. All gas turbine manufacturers can provide sound power level estimates for each of these sources.

2.8 Electric Motors¹

Electric motors used in commercial building are usually either a total enclosed fan-cooled (TEFC) motor or an open drip-proof motor (DRPR):

TEFC Motors The normalized unweighted sound pressure levels for TEFC motors follow approximately the following relationships:

$$L_p = 17 + 17 \log \text{ kW} + 15 \log \text{ rpm} \quad (14)$$

for power ratings under 37 kW, and

$$L_p = 28 + 10 \log \text{ kW} + 15 \log \text{ rpm} \quad (15)$$

for power ratings above 37 kW, where “kW” is the nameplate motor range and rpm (revolutions/minute) is the motor shaft speed. For motors above 300 kW, the calculated noise value for a 300-kW motor should be used. Equation (15) is not applicable to large commercial motors in the power range of 750 to 4000 kW. The octave band adjustments for TEFC motors are given in Table 17. Some TEFC motors produce strong tonal sounds in the 500-, 1000-, or 2000-Hz octave bands because of the cooling fan blade frequency. The octave band frequency adjustments of Table 17 allow for a moderate amount of these tones, but a small percentage of motors may still exceed these calculated levels by as much as 5 to 8 dB. When specified, motors that are quieter than these calculated values by 5 to 10 dB can be purchased.

DRPR Motors The normalized unweighted sound pressure levels for DRPR motors follow approximately the following relationships

$$L_p = 12 + 17 \log \text{kW} + 15 \log \text{rpm} \quad (16)$$

for power ratings under 37 kW, and

$$L_p = 23 + 10 \log \text{kW} + 15 \log \text{rpm} \quad (17)$$

for power ratings above 37 kW. For motors above 300 kW, the calculated noise value for a 300-kW motor should be used. The octave band adjustments for DRPR motors are given in Table 18.

2.9 Steam Turbines¹

Steam turbines are sometimes used as primary or backup drivers for chillers, pumps, and air compressors. The noise levels of steam turbines are found generally to increase with increasing power rating, but it has not been possible to attribute any specific noise characteristics with speed or turbine blade passage frequency. Suggested normalized sound pressure

levels for steam turbines, with a power range of 370 to 11,000 kW, are given in Table 19.

2.10 Transformers¹

Transformer manufacturers commonly provide an average A-weighted sound pressure level for their products. Typically, this is an average of the sound pressure levels, on a reference sound producing surface space at a distance of 0.3 m from the outline of the transformer. On the basis of field studies of many transformer installations, the sound power level in octave bands has been related to the average A-weighted sound pressure level and the area of the four side walls of the unit. This relationship is expressed by

$$L_W = \text{average } L_{pA} + 10 \log A + C + 10 \quad (18)$$

where A is the total surface of the four side walls of the transformer in the square metres and C is an octave band correction that has different values for different uses, as shown in Table 20. If the exact dimensions of the transformer are not known, an approximation will suffice. If in doubt, the area should be estimated on the high side. An error of 25% in area will produce a change of 1 dB in the sound power level. The most nearly applicable C value from Table 20 should be used. The C_1 value assumes normal radiation of sound. The C_2 value should be used in regular-shaped confined spaces where standing waves will likely occur, which typically may produce 6 dB higher sound pressure levels at the transformer harmonic frequencies of 120, 240, 360, 480, and 600 Hz (for 60-Hz line frequency; or other sound frequencies for other line frequencies). The C_3 value is an approximation of the noise of a transformer that has grown noisier (by about 10 dB) during its lifetime. This happens occasionally when the laminations or tie bolts become loose, and the transformer begins to buzz or rattle. In a highly critical location, it would be wise to use this value. Field measurements have shown that transformers may actually have A-weighted sound pressure levels that range from a few decibels (2 or 3 dB) above to as much as 5 or 6 dB below the quoted

Table 19 Normalized Sound Pressure Levels for Steam Turbines

^a Use C_1 for outdoor location or for indoor location in a large mechanical room (over 140 m³) containing many other pieces of mechanical equipment that serve as obstacles to diffuse sound and breakup standing waves.

^b Use C_2 for indoor locations in transformer vaults or small rooms (under 140 m³) with parallel walls and relatively few other large-size obstacles that can diffuse sound and breakup standing waves.

^c Use C_3 for any location where a serious noise problem would result if the transformer should become noisy following its installation and initial period of use

A-weighted sound pressure level. Quieted transformers that contain various forms of noise control treatments can be purchased at as much as 15 to 20 dB below normal A-weighted ratings.

3 PROPAGATION OF AIRBORNE NOISE FROM MECHANICAL EQUIPMENT ROOMS

The analysis of the impact of mechanical equipment, on surrounding spaces is relatively straightforward.⁵ Once the sound pressure level within the mechanical equipment room has been established, the degree of transmission to adjacent spaces can be determined with knowledge of the transmission loss properties of the walls, floor, and ceiling of the mechanical room and the acoustical properties of the adjacent room.

3.1 Transmission Loss of Mechanical Room Partitions

Transmission loss data for different partitions can be found in many publications. As a general rule this information is derived from laboratory measurements (e.g., ASTM E90-04).⁶ However, due to measurement limitation, transmission loss data below 100 Hz is rarely reported. Large mechanical equipment will often produce significant acoustic energy below 100 Hz. Therefore, there is a need to obtain transmission loss performance below 100 Hz, or alternatively, estimate the low-frequency performance. Quite often a single-number rating, such as the sound transmission class (STC) is provided. However, most of these single-number classifications are heavily weighted toward the 500- to 2000-Hz frequency range. While this range is suitable for the evaluation of isolation for speech, some music, and most transportation noise sources,

it is not suitable for the evaluation of mechanical equipment noise sources. An alternative rating called the mechanical transmission class (MTC) may be used for rating partition transmission loss for mechanical equipment. The determination of the MTC is similar to the STC in that it uses the same reference curve and measured one-third octave band transmission loss data. The determination of the MTC rating differs from the determination of the STC rating in that:

1. No deficiencies are allowed in the 125- and 160-Hz one-third octave bands.
2. Moreover, if there are any surpluses above the STC contour in the 125- and 160-Hz one-third octave bands, the rating is increased by one-third of the sum of the surpluses.

Studies have indicated that, when the A-weighted sound pressure level within the mechanical equipment room is less than the sum of the MTC rating of the partition and the room criterion (RC) rating of the background sound within the adjacent room, the intrusive noise should be acceptable. MTC ratings are useful as a cursory evaluation technique. Final selection of partition types should be based on a more complete analysis (e.g., octave or one-third octave band analysis).

3.2 Openings in Walls

An opening, such as a door, window, or louvered vent, in an exterior wall of a noisy room will allow noise to escape from that room and perhaps be disturbing to neighbors. The sound power of the sound that passes through the opening can be estimated from

$$L_W = L_p + 10 \log A \quad (19)$$

where L_p is the sound pressure level in the room at the location of the opening and A is the area, in square metres, of the opening. For normal openings (windows or vents) without ducted connections to the noise source, it may be assumed that the sound radiates freely in all directions in front of the opening.

4 VIBRATION ISOLATION OF MECHANICAL EQUIPMENT¹

If mechanical equipment is not provided with proper vibration isolation, acoustic energy will be transmitted into the supporting structure resulting in unwanted vibration and structure-borne sound. The isolator types and isolation guidelines presented in this chapter are based on experience with successful installation of mechanical equipment in commercial buildings.

4.1 Isolator Types and Transmissibility

A transmissibility curve is often used to indicate the general behavior of a vibration-isolated system. Transmissibility is roughly defined as the ratio of the force transmitted through the isolated system to the supporting structure to the driving force exerted by the piece of vibrating equipment. Strict interpretation

Table 21 Suggested Schedule for Estimating Relative Vibration Isolation Effectiveness of a Mounting System

Ratio of Driving Frequency of Source to Natural Frequency of Mount	Degree of Vibration Isolation
Below 1.4	Amplification
1.4–3	Negligible
3–6	Low
6–10	Fair
Above 10	High

of transmissibility data and isolation efficiencies, however, must be adjusted for real-life situations. Usually, floors that have large column spacing will have larger deflections than floors of shorter column spacing.

The *static deflection* (SD) of a mount is simply the difference between the free-standing height of the uncompressed, unloaded isolator and the height of the compressed isolator under its static load. This difference is easily measured in the field or estimated from the manufacturer's catalog data. For this reason it is often most beneficial to specify the static deflection for the vibration isolation system, taking into account the type of isolator, the linearity of the isolator system, and the rigidity of the structure of the equipment base and supporting structure.

Table 21 provides a suggested schedule for achieving various degrees of vibration isolation in normal construction. This table is based on the transmissibility curve but suggests operating ranges of the ratio of driving frequency to natural frequency (f_n) as define by

$$f_n = 15.77 \sqrt{\frac{1}{SD}} \quad (20)$$

where SD is in millimetres.

The terms *low*, *fair*, and *high* are merely word descriptors, but they are more meaningful than such terms as 95 or 98% isolation efficiency, which are clearly erroneous if they do not take into account the mass and stiffness of the floor slab. Vibration control recommendations given in this chapter are based on the application of this table. Table 22 lists the principal types of vibration isolators used in the isolation of building mechanical equipment and their general range of applications:

Steel Spring Isolators Steel springs are used to support heavy equipment and to provide isolation for the typical low-frequency range of about 3 to 60 Hz (180- to 3600-rpm shaft speed). Steel springs have natural frequencies that fall in the range of about 1 Hz (for approximately 254-mm static deflection) to about 6 Hz (for approximately 6-mm static deflection). Springs can transmit high-frequency vibrational energy. For this reason springs are often used in series

with a neoprene, compressed glass fiber, or cork-pad-type isolator when used to support equipment directly over critical locations in a building. Unhoused “stable” steel springs have a diameter that is about 0.8 to 1.2 times their compressed height. They have a horizontal stiffness that is approximately equal to their vertical stiffness; therefore, they do not have a tendency to tilt sideways when a vertical load is applied.

Neoprene-in-Shear Isolators Neoprene is a long-lasting material that, when properly shaped, can provide good vibration isolation for the conditions shown in Table 22. The mount usually has an interior hollow space that is conically shaped. The total effect of the shaping is that for almost any direction of applied load, there is a shearing action on the cross section of neoprene. A solid block of neoprene in compression is not effective as a vibration isolator. Manufacturers' catalogs will show the upper limit of load-handling capability of neoprene-in-shear mounts. Two neoprene-in-shear mounts are sometimes constructed in series in the same supporting bracket to provide additional static deflection. This is the double-deflection mount referred to in Table 22.

Compressed Glass Fiber Blocks of compressed glass fiber serve as vibration isolators when properly loaded. The manufacturers have several different densities available for a range of loading conditions. Typically, a block is about 50 mm thick and has an area of about 60 to 130 cm², but other dimensions are available. These blocks attenuate high-frequency structure-borne noise, and they are often used alone, at various spacings, to support floating concrete floor slabs. The manufacturer's data should be used to determine the density and area of a block required to achieve the desired static deflection. Unless otherwise indicated, a static deflection of about 5 to 10% of the uncompressed height is normal. With longtime use, the material may compress an additional 5 to 10% of its height. This gradual change in height must be kept in mind during the designing of floating floors to meet floor lines of structural slabs.

Ribbed Neoprene Pads Neoprene pads with ribbed or waffle pattern surfaces are effective as high-frequency isolators. In stacks of 2 to 4 layers, with each layer separated by a metal plate, they are also used for vibration isolation of low-power rotary equipment. The pads are usually about 6 to 10 mm thick, and they compress by about 20% of their height when loaded at about 140 to 350 kPa. Higher durometer pads may be loaded up to about 700 kPa. The pads are effective as isolators because the ribs provide some shearing action, and the spaces between the ribs allow lateral expansion as an axial load is applied. The manufacturer's literature should be used for proper selection of the material (load-deflection curves, durometer, surface area, height, etc.).

Felt Pads Felt strips or pads are effective for reducing structure-borne sound transmission in the mounting of piping and vibrating conduit. One or more

Table 22 General Types of Applications of Vibration Isolators^a

Isolator Type	Typical Range of Static Deflection (mm)	Approx. Range of Natural Frequency (Hz)	Vibration Isolation Applications, Nonspecific

Air spring	—	10 to 1	See text for applications and limitations.			

^aSee text for additional information on isolator types and specific equipment installations.

^bCritical locations are those that should have a noise level of NC 35 or lower and noncritical locations are those that can allow a noise level of NC 40 or higher.

^cAlways use pad-type isolator in series with spring to control high-frequency structure-borne noise in critical locations.

^dSpecial design required for reciprocating equipment at critical locations, especially for low speeds.

^eNot normally recommended for this application but can be adapted as special design.

^fMay be used alone for relatively high-speed rotary equipment or in series with steel springs in critical locations for reduction of high-frequency structure-borne noise. Not normally used alone for vibration isolation of reciprocating equipment.

layers of 3- or 6-mm-thick strips should be wrapped around the pipe under the pipe clamps that attach the piping to building structures. Felt pads will compress under long-duration and high-load application and should not be used alone to vibration isolate heavy equipment.

Air Springs Air springs are the only practical vibration isolator for very low frequencies, down to about 1 Hz or even lower for special applications. An air mount consists of pressurized air enclosed in a resilient reinforced neoprene chamber. Since the air chamber is subject to slow leakage, a system of air mounts usually includes a pressure sensing system and external air supply. A group of air mounts can be arranged to maintain very precise leveling of a base by automatic adjustment of the pressure in the individual mounts. Specific design and operation data should be obtained from the manufacturer.

4.2 Mounting Assembly Types

In this section, five basic mounting systems are described for the vibration isolation of equipment. These mounting systems are applied to specific types of equipment in Section 4.3.

Type I Mounting Assembly The equipment should be mounted on an array of *pad mounts*. The pads may be of compressed glass fiber or of multiple layers of ribbed neoprene or waffle pattern neoprene of sufficient height and of proper stiffness to support

Figure 2 Type I mounting assembly.

the load while meeting the required static deflection (see Fig. 2).

Type II Mounting Assembly The equipment or the assembly of equipment should be mounted on a steel frame that is stiff enough to allow the entire assembly to be supported on flexible point supports without fear of distortion of the frame or misalignment of the equipment. The frame should then be mounted on resilient mounts, steel springs, neoprene-in-shear mounts, or isolation pads, as the static deflection would require. If the equipment frame itself already has

Figure 3 Type II mounting assembly with spring mount.

adequate stiffness, no additional framing is required, and the isolation mounts may be applied directly to the base to the equipment (see Fig. 3).

Type III Mounting Assembly This mount is the same as the type I mount in all respects except that the mounting brackets and the top of the steel springs should be located as high as practical on the concrete inertia block but not necessarily as high as the vertical center-of-gravity position of the assembly (Fig. 4). The steel springs can be recessed into pockets in the concrete block, but clearances around the springs should be large enough to assure no contact between any spring and any part of the mounted assembly. Provision must be made to allow positive visual inspection of the spring clearance. When this type of mounting is used for a pump, the concrete inertia block can be given a T-shape plan, and the pipes to and from the pump can be supported rigidly with the pump onto the wings of the T. In this way, the pipe elbows will not be placed under undue stress.

Type IV Mounting Assembly The specified equipment should be mounted rigidly on a concrete inertia block. The length and the width of the inertia block should be at least 30% greater than the length and width of the supported equipment. Mounting brackets for stable steel springs should be located off the sides of the inertia block at or near the height of the vertical center of gravity of the combined completely assembled equipment and concrete block. The clearance between the floor and the concrete inertia block shall be at least 100 mm, and provision should be

allowed to check this clearance at all points under the block. The inertia block adds stability to the equipment and reduces motion of the equipment (see Fig. 5).

Type V Mounting Assembly Large, low-speed propeller-type cooling towers located on roof decks of large buildings may produce serious vibration in the building if adequate vibration isolation is not provided. It is recommended that the entire cooling tower assembly be isolated on stable steel springs similar to the type III mount (see Fig. 4). An alternative is to only isolate the motor and fan only (see Fig. 6); however, this does not prevent water fall noise from entering the structure.

4.3 Tables of Recommended Vibration Isolation Details

Tables 23 to 34 (Ref. 1) provide suggested vibration isolation for the most commonly found mechanical equipment in commercial buildings. A common format is used for all the tables that summarize the recommended vibration isolation details for the various types of equipment. Additional comments follow.

Centrifugal and Axial-Flow Fans Ducts should contain flexible connections at both the inlet and discharge of the fans, and all connections to the fan assembly should be clearly flexible. The entire assembly should bounce with little restraint when one jumps up and down on the unit. Large ducts (cross section area over 1.5 m²) that are located within about 10 m of the inlet or discharge of a large fan (over 15 kW) should be supported from the floor or ceiling with resilient mounts having a static deflection of at least 6 mm.

^aColumn 1: Mounting type (see text).

Column 2: Minimum ratio of weight of inertia block to total weight of supported load. Applies only to mounting types III and IV.

Column 3: Minimum static deflection of stable steel springs (in mm) for indicated floor span (in m)

Reciprocating-Compressor Refrigeration Equipment These recommendations apply also to the drive unit used with the reciprocating compressor. Pipe connections from this assembly to other equipment should contain flexible connections.

Centrifugal-Compressor Refrigeration Equipment The recommended vibration isolation details for this equipment include the drive unit and the condenser and evaporator tanks.

Boilers The recommended vibration isolation for boilers is shown on Table 28. This applies for boilers with integrally attached blowers. Table 24 should be followed for the support of blowers that are not directly mounted on the boiler. A flexible connection or a thermal expansion joint should be installed in the exhaust breaching between the boiler and the exhaust stack.

Motor-Pump Assemblies Electrical connections to the motors should be made with long “floppy”

“No” means “Not recommended for these conditions.”

lengths of flexible armored cable, and piping should be resiliently supported. For most situations, a good isolation mounting of the piping will overcome the need for flexible connections in the pipe. An important function of the concrete inertia block (type II mounting) is its stabilizing effect against undue bouncing of the pump assembly at the instant of starting. This gives better longtime protection to the associated piping. These same recommendations may

be applied to other motor-driven rotary devices such as centrifugal-type air compressors and motor-generator sets in the power range up to a few hundred kilowatts.

Steam Turbines Table 32 provides a set of general isolation recommendations for steam-turbine-driven rotary equipment, such as gears, generators, or centrifugal-type gas compressors. The material given in Table 26 applies when a steam turbine is used to drive centrifugal-compressor refrigeration equipment.

The recommendations given in Table 24 apply when a steam turbine is used to drive reciprocating-compressor refrigeration equipment or reciprocating-type gas compressors.

Gears When a gear is involved in a drive system, vibration isolation should be provided in accordance with recommendations given for either the main power drive unit or the driven unit, whichever imposes the more stringent isolation conditions.

Transformers Power leads to and from the transformers should be as flexible as possible. In outdoor locations, earth-borne vibration to nearby neighbors is usually not a problem, so no vibration isolation is suggested. If vibration should become a problem, the transformer could be installed on neoprene or compressed glass fiber pads having 6-mm static deflection.

Air Compressors Recommended mounting details for centrifugal-type air compressors of less than 75 kW are the same as those given for motor-pump units in Table 31. The same recommendations would apply for small (under 8 kW) reciprocating-type air compressors. For reciprocating-type air compressor (with more than two cylinders) in the 8-kW to 37-kW range, the recommendations given in Table 24 apply for the particular conditions. For 8 kW to 80 kW, one- or two-cylinder, reciprocating-type air compressors, the recommendations of Table 34 apply. This equipment is a potentially serious source of low-frequency vibration in a building if it is not isolated. In fact, the compressor should not be located in certain parts of the building, even if it is vibration isolated. When these compressors are used, all piping should contain flexible connections, and the electrical connections should be made with flexible armored cable.

4.4 Vibration Isolation: Miscellaneous

It is good practice to isolate all piping in the mechanical equipment room that is connected to vibrating equipment with resilient ceiling hangers or from floor-mounted resilient supports. As a general rule, the first three pipe supports nearest the vibrating equipment should have a static deflection of at least one-half the static deflection of the mounting system used with that equipment. Beyond the third pipe support, the static deflection can be reduced to 6 or 12 mm for the remainder of the pipe run in the mechanical equipment room. When a pipe passes through the mechanical equipment room wall, a minimum 25-mm clearance should be provided between the pipe and the hole in the wall. The pipe should be supported on either side of the hole, so that the pipe does not rest on the wall. The clearance space should then be stuffed with fibrous filler material and sealed with a nonhardening caulking compound at both wall surfaces. Vertical pipe chases through a building should not be located beside acoustically critical areas. If they are located beside critical areas, pipes should be resiliently mounted from the walls of the pipe chase for a distance of at least 3 m beyond each such area, using both low-frequency

and high-frequency isolation materials. Pipes to and from the cooling tower and the associated mechanical equipment room should be resiliently supported for their full length between the cooling tower and the associated mechanical equipment room. Steam pipes should be resiliently supported for their entire length of run inside the building. Resilient mounts should have a static deflection of at least 12 mm.

Whenever a steel spring isolator is used, it should be in series with a neoprene isolator. For ceiling hangers, a neoprene washer or grommet should also be included; and if the pipe hangers are near a very critical area, the hanger should be a combination hanger that contains both a steel spring and a neoprene-in-shear mount. During inspection, the hanger rods should be checked to ensure they are not touching the sides of the isolator housing and thereby shorting-out the spring.

To be at all effective, a flexible pipe connection should have a length that is approximately 6 to 10 times its diameter. Tie rods should not be used to bolt the two end flanges of a flexible connection together. Flexible connections are either of the bellows type or are made up of wire-reinforced neoprene piping, sometimes fitted with an exterior braided jacket to confine the neoprene.

When a mechanical equipment room is located directly over or near a critical area, it is usually desirable to isolate most of the "nonvibrating equipment" with a simple mount made up of one or two pads of neoprene or a 25- or 50-mm layer of compressed glass fiber. Heat exchangers, hot water heaters, water storage tanks, large ducts, and some large pipe stands may not themselves be noise sources, yet their pipes or their connections to vibrating sources transmit small amounts of vibrational energy that they then may transmit into the floor. A simple minimum isolation pad will usually prevent this noise transfer.

CHAPTER 113

NOISE CONTROL IN U.S. BUILDING CODES

Gregory C. Tocci
Cavanaugh Tocci Associates, Inc.
Sudbury, Massachusetts

1 INTRODUCTION

The purpose of this chapter is to provide an overview of building codes in the United States. Building codes in Europe are covered in Chapter 114. These are covered separately as the origination and applicability of noise control provisions in U.S. building codes are different from those of Europe. Generally speaking, U.S. building codes are developed and promoted by private organizations and adopted by jurisdictions as determined by state law. Yet, not all jurisdictions have building codes or noise control provisions. A few larger cities have developed their own codes with provisions that differ from codes of their home states.

Nevertheless, building codes set standards of quality and uniformity for all aspects of building construction. Building codes have been in use since before the 1900s. Since the development of a comprehensive code covering all aspects of building construction exceeded the technical abilities of most cities, even large cities, several organizations were formed between 1920 and 1940 to serve the needs of building regulators in cities and towns. A large part of the work of these organizations was to develop model building codes that could be used by participating localities and states. Unlike Europe, where building codes have been developed and enforced by governmental agencies, building codes in the United States have been developed by organizations of building officials and adopted as law as appropriate by jurisdictions. At the close of the twentieth century, there were three main building code organizations that represented most U.S. jurisdictions. These were as follows:

- Building Officials and Code Administrators International (BOCA).
- International Conference of Building Officials (ICBO).
- Southern Building Code Congress International (SBCCI)

In the latter part of the 1990s, these three organizations merged to form the International Code Council (ICC). It was the objective of the ICC to assemble a new model code from portions of the BOCA, ICBO, and SBCCI model codes. In so doing, it has created separate model codes for buildings (architectural and structural), mechanical systems, plumbing systems, fire, and electrical. Noise provisions in the original three codes fit into the building (architectural and structural) codes. It was the decision of the ICC to adopt the BOCA provisions for noise in buildings

and omit adopting any of the existing provisions from both the ICBO and the SBCCI model codes. All three of the former model codes were discussed in detail in the *Encyclopedia of Acoustics*.¹

The International Building Code (IBC), as with its predecessor codes, is available for adoption in whole or in part, and/or amended by jurisdictions. Most often, these jurisdictions are state legislatures, but sometimes they are county governments or smaller jurisdictions.

The federal government does not require states or localities to have building codes. Federal agencies use their own building codes or use the IBC for their own projects. The International Code Council is a private organization and has as its membership building code officials. The ICC serves its membership by producing bodies of code that are adopted by states and localities and administered by the membership. Hence, a large part of the activity of ICC is to educate its membership in code practices and enable them to make judgments regarding the conformance of building construction to code requirements.

There are many jurisdictions in the United States that do not have building codes. Others have their own building code, for example, New York City and Chicago. Each state determines whether it will adopt the building code on a statewide basis or leave it to the localities to make the decision whether or not to adopt a building code. The noise control provisions of the IBC are contained in Chapter 12 of the code as discussed below. Changes and additions to the IBC noise provisions adopted by California are discussed as examples of the wide latitude in changes that jurisdiction may take. However, it is unusual for jurisdictions to make changes or omit in whole noise control provisions of the IBC. For comparison, the noise control provisions of the New York City building code are also described later in this chapter.

2 TYPES OF NOISE LIMITS

Noise ordinances, regulations, criteria, and standards are promulgated by jurisdictions to serve the needs of those jurisdictions. Cities and towns publish noise ordinances that appear as part of their town regulations or in their zoning or planning bylaws. These regulations are usually *imission* type regulations in that they typically control environmental sound by limiting sound that a source may produce at a *receptor* location.

Emission-type limits set constraints on sound produced by a *source*. Emission limits are more prevalent among agencies setting standards for specific sound-source producing industries. Often, these are expressed using descriptors other than sound pressure

level; for example, sound power level is sometimes used.

Many federal agencies have noise regulations, but these are usually intended only to apply to sources and receptors affected by projects funded by those agencies and are not generally applicable to all projects or facilities. The U.S. Environmental Protection Agency (U.S. EPA) has not set general environmental sound pressure level limits but has identified sound pressure levels that protect public health and welfare with a margin of safety and has set limits on specific types of equipment such as trucks and air compressors.

U.S. building codes are intended to set standards to ensure construction quality. Most prevalent among these are lower limits on the sound isolation performance of sound-isolating constructions. The implication is that building codes tend to be imission-type standards. This is true of the IBC. However, as seen in the New York City building code, emission limits do also appear in some codes as well.

This chapter discusses noise limits that appear in the 2003 IBC model building code.² They are limits for which the local building official is obligated to judge as having or having not been met. The local building official is normally not obligated to evaluate conformance of building construction with noise limits that are not part of the building code. For example, a building official may not be explicitly required to evaluate the conformance of noise produced by a rooftop unit at nearby residential property in accordance with a municipal noise limit; however, he or she would have the authority to do so if judged to be prudent by that official.

3 NOISE REGULATION FORMAT

Noise regulations share several facets. These are as follows:

1. *Status.* Every standard states whether it is voluntary or obligatory, and, if it is obligatory, under what circumstances individuals or organizations must conform to the standard.
2. *Object.* Every standard is devised to limit sound exposure at a receiver or to limit sound emitted by a source.
3. *Scope.* Every standard will indicate the specific type of noise exposure and condition under which the ordinance is applicable.
4. *Limit.* Every standard expresses its limits either as numerical values for one or more noise descriptors or in some other specific way such as establishing hours of operation or in some subjective manner such as not allowing noise that constitutes an "annoyance."
5. *Evaluation.* Every standard should indicate the means by which conformance can be objectively established.

4 INTERNATIONAL BUILDING CODE (IBC)

The following is a detailed discussion of the noise control provisions of the IBC. The full code text

can be obtained from the International Code Council (www.iccsafe.org). The noise control provision for sound appears in Section 1207, Sound Transmission. Since the noise control provisions are part of the body of the IBC, its *status* is obligatory; that is, a state or locality that adopts the IBC must include this section on building noise control or pass specific legislation to remove or modify it.

The *object* of IBC Section 1207 is the receiver; that is, it seeks to limit noise at a receptor as opposed to controlling sound emitted by a source. The scope of the code is limited to the sound isolation performance of "all common interior walls, partitions, and floor/ceiling assemblies between adjacent dwelling units or between a dwelling unit and adjacent public areas..." Note that this section of the IBC only addresses sound transmission between dwelling units even though the code covers all types of building construction.

The *scope* of Section 1207 includes the airborne and impact sound isolation performance of constructions separating dwelling units. The airborne sound isolation performance *limit* is expressed as minimum party wall and floor/ceiling sound transmission class (STC) rating of 50, if such rating has been determined on the basis of sound transmission loss measured in a laboratory, or 45 if determined from noise reduction measured in the field. Similarly, the impact sound isolation performance *limit* is expressed as a minimum floor/ceiling impact isolation class (IIC) rating of 50, if such rating has been determined on the basis of impact sound pressure levels produced by an ISO tapping machine and measured in a laboratory, or 45 if determined from tapping machine sound pressure levels measured in the field.

The reference standards imply that the *evaluation* of a building assembly can be made by a building official by comparing proposed or constructed partition and floor/ceiling assemblies with lists of tested assemblies. It specifically references a publication dated 1944, which does not provide STC ratings; however, there are many agency and commercial publications that provide such information. Hence, the code does not explicitly require the involvement of an engineer or some other professional and does not require testing, but permits testing for unrated assemblies or where performance may be in question. Only American Society for Testing and Materials (ASTM) laboratory tests for sound transmission loss and impact isolation are cited. The corresponding ASTM field tests are not cited.

5 STATE ADOPTIONS OF IBC NOISE PROVISIONS

5.1 California

States and other jurisdictions sometimes modify code limits and/or formats. This is true of acoustical provisions as well, although it is quite rare. The State of California has made modifications to the IBC on sound transmission by adding provisions to the IBC limits and adding new limits.

The California building code is contained in the California Code of Regulations, Title 24, Part 2,

Volume 1.³ The California building code section on sound transmission is similar to the IBC section but differs in four ways. First, the California code provides more detail regarding the application of STC and IIC ratings. For example, it provides definitions and lists applicable standards. Second, it expands the application of residential limits to other residential-type spaces such as hotel guest rooms and other residential-type occupancies. Third, it is more specific about how and by whom field testing is to be conducted, and the types of sound isolation descriptors that should be measured. This includes specifying a minimum STC rating of 26 for corridor doors and minimum composite STC rating of 30 for corridor walls with doors. And fourth, it establishes a limit for sound inside residential spaces produced by exterior noise sources such as highway traffic and aircraft.

The California amendment on interior sound pressure level produced by exterior noise is expressed as a day–night average sound pressure level (DNL) not to exceed 45 dB. The standard permits the alternative use of the community noise exposure level (CNEL) and indicates that the interior CNEL sound pressure level must also not exceed 45 dB. The day–night average sound pressure level is the 24-h equivalent sound pressure level with a 10-dB penalty added to sound pressure levels occurring between 10 p.m. and 7 a.m. The community noise exposure level is similar in that it is a 24-h equivalent sound pressure level, but with a 5-dB penalty applied to sound pressure levels occurring between 6 p.m. and 10 p.m., and a 10-dB penalty applied to sound pressure levels occurring between 10 p.m. and 7 a.m. The California code expresses a preference for use of the DNL but permits the use of the CNEL.

A building official responsible for evaluating the conformance of a building with California code sound limits may do so by comparing wall and floor–ceiling assemblies with those assemblies listed in Appendix Chapter 12, Section 1208A.4.2. Or the official can request certification through field testing by an acoustician. The acoustician can judge conformance or nonconformance of a building construction to the code through the use of one or more of the following noise descriptors:

- Noise isolation class (NIC)
- Normalized noise isolation class (NNIC)
- Field impact insulation class (FIIC)
- Normalized A-weighted sound pressure level difference (D_n)

The NIC, NNIC, and FIIC are defined in ASTM standards. The D_n is described in Appendix Chapter 12, Section 1208A.4.2 of the California code.

The Appendix Chapter 12 evaluation of interior sound pressure levels requires an acoustical analysis to be conducted before construction if the DNL or the CNEL exceeds 60 dB. The standard also alternatively requires an evaluation report by an acoustician after construction is completed.

5.2 New York City

New York City has its own building code and does not reference the IBC or its predecessors; however, it is similar in its requirements to both the IBC and its predecessors. The first modern building code for the City of New York was enacted in 1938. It was replaced by a “new code” in 1968. The noise control provisions of the Building Code of the City of New York are contained in Title 27, Construction and Maintenance, Subchapter 27, Article 9, Noise Control in Multiple Dwellings.⁴ The *object* of the city code Article 9 is the receiver. The *scope* of the code includes the sound isolation performance of party walls and floor–ceiling assemblies between dwelling units or between a dwelling units and adjacent public and utility areas.

The airborne sound isolation performance *limit* is a minimum party wall and floor–ceiling STC rating of 50, if such rating has been determined on the basis of sound transmission loss measured in a laboratory, or 48 if determined from noise reduction measured in the field. The code requires that the entrance door to dwelling units have an STC rating of not less than 35. Additionally, the code provides recommendations on the treatment of wall penetrations and the like to avoid compromising airborne sound isolation performance.

The impact sound isolation performance *limit* is expressed as a minimum floor–ceiling impact noise rating (INR) of 50, if such a rating has been determined on the basis of impact sound pressure levels produced by an ISO tapping machine and measured in a laboratory, or –2 if determined from tapping machine sound pressure levels measured in the field. Note that the INR is no longer used and is approximately as follows:

$$\text{INR} \cong \text{IIC} - 51$$

where the INR is the impact noise rating and IIC is the impact isolation class rating.

The reference standards imply that the *evaluation* of a building assembly can be made by a building official by comparing proposed or constructed partition and floor–ceiling assemblies with lists of tested assemblies.

The code also sets limits on sound produced by various building noise sources and provides guidelines for equipment vibration isolation. The only receptor limit provided is that sound produced by exterior building equipment transmitted to inside dwelling units must not exceed NC-35.

The code also limits the amount of sound that building mechanical equipment can produce. It sets limits on the sound power levels in mechanical spaces or shafts adjoining dwelling spaces and sound power produced by exterior mechanical equipment adjoining buildings. Both are expressed as sound power levels in octave bands 63 to 8000 Hz. In the case of exterior equipment located adjacent to other buildings, the permitted sound power levels are also given for various distances between source equipment and receptor buildings.

6 COMPARISON OF BUILDING CODES

Table 1 summarizes the provisions of the International Building Code, the California building code Section 1208 on sound transmission control, and the City of New York Subchapter 12, Article 9, on noise control. The provisions of all three codes are similar with respect to airborne sound isolation with some differences as noted.

7 GUIDE TO BUILDING NOISE CRITERIA

Conformance with building code requirements for sound isolation does not always ensure that the expectations of occupants of a building will be met. When providing assistance to an architect or owner of a new building, the acoustical consultant must recognize this and be vigilant in identifying those situations where occupants will expect greater building sound isolation performance. It is this author's experience that buildings in which sound isolation complaints have occurred have often had sound isolation characteristics that conform to minimum code requirements. Perhaps the most common instance of complaints is one where a family sells a single-family home in a quiet suburb and

moves to a more expensive condominium, many times in a more urban setting. Having been swayed by their perceived quality of the condominium's fit and finish, as well as the unit's cost, and having lived for many years in a single-family home, the reality of hearing sounds from adjacent units and/or mechanical equipment sound often becomes a source of disappointment and complaints. The acoustical consultant must guide the architect in avoiding this pitfall by providing recommended sound isolation performances that meet the likely expectations of future occupants while fitting within the reality of budget constraints.

Table 2 presents a guide for establishing sound isolation criteria for three categories of residential construction defined as minimally sensitive, moderately sensitive, and highly sensitive. These sensitivities are of persons occupying multiresidential buildings. Persons of minimal sensitivity in this context are those not expecting special qualities in building performance or do not anticipate intensive use of their living unit for activities requiring quiet, for example, studying or intently listening to quiet music. High ambient sound pressure levels produced by mechanical systems are typical of living units served by window air conditioners. High ambient

	DNL or CNEL ≥ 45 dB	Maximum sound power levels specified for mechanical equipment
<i>Evaluation</i>		
Comparison with listed assemblies	Comparison with listed assemblies and report by acoustical consultant (testing if assembly not listed)	Comparison with listed assemblies

sound pressure levels are common in buildings overlooking major highways and with windows providing low noise reduction because of lightweight glazing and/or because of poor window gaskets.

Persons of moderate sensitivity would expect good speech privacy and low enough ambient sound pressure levels to ensure uninterrupted intelligibility of spoken and television speech at moderate levels. Mechanical systems serving these units would require sound attenuation. In noisier urban areas, acoustical windows may be required to sufficiently control exterior sound transmission into living areas. Achieving the IIC ratings in Table 2 would require standard carpeting or fairly sophisticated hard-finished floor systems incorporating resilient underlayments.

Persons falling in the highly sensitive category would expect minimally audible airborne and impact sound transmission from adjacent units, good speech intelligibility for low-level signals, and an ability to play moderately loud music without disturbing neighbors. Even in quiet environs, acoustical windows may be required. Special attention must also be paid to controlling noise from mechanical systems serving these living units. Achieving the IIC rating indicated in Table 2 would require carpeting or floated hard-finished floors. Floated floors would be characterized as a concrete or other heavy construction isolated from the building structural floor by vibration isolation elements.

To achieve building floor–ceiling constructions that provide IIC ratings of 50 or higher generally requires special construction details including resilient floor underlayments (or floated floor constructions) and sound isolation ceilings. IIC ratings higher than 65 are generally easily obtained by using floor carpeting. As a compromise, condominium complexes sometimes create rules that permit hard-finished floors, providing they can achieve a minimum IIC rating of 50, if carpeting is used in unit walkways and halls, and if the total carpeting floor coverage is in a range of 40 to 70%.

Interior sound pressure levels produced by mechanical systems and indicated in Table 2 are consistent with the recommendations of the American Society

of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE).⁵ Tonal sound, such as that produced by transformers and other electrical equipment, may need to adhere to lower sound pressure level limits than indicated for mechanical systems. This is also true for transient sound, such as sound produced by elevators.

The suggested criteria for environmental sound in Table 2 apply to transportation sound, that is, sound produced by road traffic, aircraft, and railroads. The criteria may not be suitable for industrial noise or weapons firing sound, for example.

The information of Table 2 is to be used only as a general guide for setting criteria and should not be included in building project specifications without further consideration of project needs, feasibility, and local code requirements. The interpretation of sensitivity for categorizing residential occupancies must be done with care, and individual circumstances may influence categorizations.

8 SUMMARY

In the last 10 years much has changed in U.S. building codes. The three former code organizations—Building Officials and Code Administrators International (BOCA), International Conference of Building Officials (ICBO), and Southern Building Code Congress International (SBCCI)—have collaborated to form a new code organization—the International Code Council (ICC). The three model codes have been withdrawn from use and the new International Building Code (IBC) has been promoted by the three organizations. The IBC is generally comprised of the portions of each of the three former model codes. The IBC acoustical limits appear in Section 1207, Sound Transmission. This code section most closely matches that of the BOCA code on sound, except that the IBC code sets minimum STC and IIC ratings of 50, instead of 45, for party wall and floor–ceiling constructions of residential units in multiresidential buildings.

The ICC increase of STC and IIC rating limits from 45 to 50 has brought sound isolation performances up to general expectations in this author's experience.

Table 2 Guidelines for Acoustical Criteria in Multiresidential Buildings

Sound Isolation Type	Minimally Sensitive	Moderately Sensitive	Highly Sensitive
Party wall/floor sound isolation			
Wall and floor sound isolation (STC rating)	50	55	60 ^a
Floor impact sound isolation (IIC rating)	50	55	60 ^a
Mechanical equipment sound isolation (Criteria curve, NC, RC)			
Sleeping rooms	35	30	20
All other rooms	40	35	25
Exterior environmental sound isolation			
Exterior environmental sound pressure levels inside units (day–night average sound pressure level in dB)	45	35	25
Maximum exterior environmental A-weighted sound pressure level inside unit (measured with meter slow response)	65	55	45

^aHigher values may at times be desired or required, but these represent the general limits of modern construction normally encountered in the United States, with the exception that the IIC rating of floor–ceiling constructions can be increased beyond what is shown if carpet is used on floors.

Market rate properties nevertheless generally require higher STC and IIC ratings on the order of 55 as suggested in Table 2 for moderate sensitivity to noise.

The IBC still lacks the exterior facade/fenestration limits of the California building code and of building codes of several European countries. Programs to establish compatible land-use zoning around airports and other noise-producing activities have been widely established. Nevertheless, economic and social pressures are still causing noise-sensitive building development to occur near major noise sources. Today, construction of residential subdivisions within a few feet of major highways and in areas affected by noise is still common. Oddly enough, sometimes the attraction of noisy sites for development is the source itself, that is, the convenience of being near a highway or an airport. Hence, the only way to protect the eventual building occupant is for jurisdictions to incorporate exterior facade/fenestration sound isolation provisions into their building codes.

ACKNOWLEDGMENTS

The author wishes to thank Brion G. Koning, Cavanaugh Tocci Associates, for his assistance in

gathering information for this chapter. Finally, the author thanks Solutia for its support in gathering U.S. building code information.

CHAPTER 114

SOUND INSULATION OF RESIDENTIAL HOUSING – BUILDING CODES AND CLASSIFICATION SCHEMES IN EUROPE

Birgit Rasmussen
SBI, Danish Building Research Institute
Hørsholm, Denmark

1 INTRODUCTION

Most countries in Europe have legal sound insulation requirements for dwellings. However, fulfillment of legal requirements does not ensure satisfactory conditions, and for this reason classification schemes have been introduced in several countries to meet the need to specify a higher level of acoustical comfort than prescribed by the legal requirements. It is important to observe that acoustical comfort for a person is related to the person both as a receiver of sound but also as a source of sound. It can be annoying to be exposed to noise from the neighbors, but it can be equally annoying to know that your activities can be heard by other people, implying lack of privacy or causing annoyance. The classification schemes define a number of classes, which are intended to reflect different levels of acoustical comfort. While requirements for sound insulation between dwellings have existed approximately 50 years in several countries, it is only during the last few decades that facade sound insulation requirements have become common in Europe. At the same time there is a focus on creating improved acoustical environments. The aim of current noise policy in Europe is to reduce the noise exposure of people in order to avoid adverse effects. Within building acoustics, the international (ISO) standards for laboratory and field measurements are implemented as European (EN) standards. A few years ago, EN standards for prediction of sound insulation in buildings were developed and subsequently published as ISO standards.

2 ACOUSTICAL COMFORT IN DWELLINGS

Acoustical comfort can be characterized as follows:

- Absence of unwanted sound
- Desired sounds having the right level and quality
- Opportunities for acoustical activities without being heard by or annoying other people

Poor sound insulation between dwellings can be a cause of conflicts and a cause of restraints of activities.¹

To achieve acoustical comfort in a dwelling, certain requirements have to be fulfilled concerning:

- Airborne sound insulation
- Impact sound insulation
- Noise level from traffic and industry
- Noise from building services and equipment

It has often been claimed that people want good sound insulation but are not willing to pay extra to get it. In 1995 an investigation was made in Sweden to find the desired level of sound insulation of new dwellings.² In all, 2322 questionnaires were used for the analysis: 65% of the participating people lived in multistory housing, 20% in detached housing, 10% in terraced housing, and 5% in other kinds of housing. One of the main questions was about the willingness to pay a higher rent if the sound insulation of the apartment could be significantly improved. In summary it can be concluded that around 60% of the population were willing to pay on average a 10% higher rent if the sound insulation of the dwelling could be improved. On the other hand, if a dwelling is expensive and marketed as “luxury,” the occupants expect a proportional sound insulation.³ Besides, there is in general an increasingly stronger request for comfort. Additional challenges are new lifestyle trends, such as bare floors, powerful home entertainment, and more flexible hours.

In spite of the fact that a dwelling is probably the biggest investment during most people’s lifetime, that much time is spent in the dwelling, and that acoustical comfort is very important to well-being, objective information about the acoustical conditions is rarely available, or it might happen that the concepts applied for quantification of the performance are not suitable. This is very unsatisfactory to prospective occupants of a dwelling, as acoustical quality is a “hidden” quality, which is not easily evaluated by other means. Fulfillment of legal requirements does not ensure satisfactory conditions, and for this reason classification schemes have been introduced in several countries to meet the need to specify a higher level of acoustical comfort than prescribed by the legal requirements. The classification schemes define a number of classes, which are intended to reflect different levels of acoustical comfort. Thus, it is, of course, important that concepts applied for evaluation of sound insulation correlate well with the subjective evaluation of the sound insulation experienced in practice. In Europe, concepts as

well as the level of requirements differ widely according to the results of a survey⁴ carried out in 24 countries in 2004. Considerations on concepts are further elaborated in Ref. 5.

In Europe there is a focus on creating improved acoustical environments, see the Environmental Noise Directive (END)⁶ and the strategy paper.⁷ The aim of current noise policy is to reduce the noise exposure of people in order to avoid adverse effects. Therefore, the policy has to consider some general principles that exist both at a technical level and at a legal level. The *legal principles* are related to noise management, other environmental issues, and sustainability.

The *technical principles* refer to the management and reduction of noise emission and exposure and have a clear ranking:

1. To avoid and reduce noise at its source (noise that is not generated cannot lead to noise exposure)
2. To reduce noise in its propagation (measures as close to the source as possible should be preferred because such measures protect the highest number of people)
3. To reduce noise at the receiver (these measures should only be used if other measures are ineffective)

Following these principles, the European Union (EU) has developed a comprehensive policy on environmental noise that is based on the two fundamentals: emission-related legislation for controlling noise at its source and the Environmental Noise Directive⁶ (END) with elements closely related to noise perception. The END⁶ defines three key elements for future noise policy that constitute a standard approach to the management of environmental noise:

- Harmonized assessment of environmental noise
- Informing and consulting the public
- Appropriate actions

The basis for the *assessment of environmental noise* is strategic noise maps, which are to be established with common noise indicators and methods. On the basis of the assessment provided by the strategic noise maps, competent authorities must draw up *action plans* to reduce noise where it is necessary, to maintain environmental noise quality where it is good, and to protect quiet areas in agglomerations. The Directive does not set any limit value, nor does it prescribe the measures to be used in the action plans, which remain at the discretion of the competent authorities.

To have widespread *information to the public* about noise exposure, its effects, and the measures considered to address noise, the most appropriate information channels should be selected. Action plans should address priorities in areas of interest and

should be drawn up by the competent authorities in *consultation with the public*.

While the END⁶ creates focus on the environments, including facades, there is no similar EU initiative concerning sound insulation between dwellings, although the above-mentioned three key elements (harmonization, information, actions) are applicable to this topic.

3 CONCEPTS FOR EVALUATION OF SOUND INSULATION

In the beginning of the twentieth century, it was realized that insufficient sound insulation could initiate conflicts between neighbors and reduce the well-being of the occupants, and thus the need for sound insulation requirements was recognized. The very first sound insulation requirements were qualitative; for example, "the building constructions shall be designed to provide sufficient sound insulation between dwellings according to the assessment made by the building commission" (example from municipal requirements in Denmark, 1936). In the middle of the twentieth century, the requirements became more specific but still were not quantified. Typically, they were comparative, for example, requiring "a sound insulation as good as a 1/1 brick wall or another construction providing at least the same sound insulation" (example from national requirements in Denmark, 1956). Later, more specific concepts appeared, for example, R_m being an arithmetic average of one-third octave values. It was only in the 1960s that several countries introduced quantified requirements referring to specific concepts and standards.

Now, at the beginning of the twenty-first century, more than 50 years after implementation of the first national sound insulation requirements in Europe, most countries in Europe have legal requirements, although the criteria and enforcement differ widely. In general, building regulations in Europe have been developed and enforced by governmental agencies. Within building acoustics, the ISO standards are implemented as European (EN) standards, and the majority of countries apply the field measurement methods described in ISO 140 parts 4, 5, 7 from 1998⁸ and the rating methods in ISO 717 from 1996.⁹ Due to the fact that ISO 717 offers a variety of concepts, several countries can keep concepts applied in the past and still refer to ISO 717, implying that the incentive to harmonization is insufficient.

The first international standard for rating of sound insulation of dwellings was ISO/R 717:1968,¹⁰ which was based on extensive investigations (see Chapter 107) and supporting field measurements according to ISO/R 140:1960.¹¹ The maximum allowable unfavorable deviation from the reference curve was 8 dB. A revised ISO 717 consisting of three parts was published in 1982¹² and the series supported the ISO 140 series published in 1978.¹³ The basic reference curves were the same as in ISO/R 717:1968,¹⁰ but the 8-dB rule was removed. However, the 8-dB rule survived partly in the 1982 revision, in the sense that the maximum deviation must be indicated in the test report, if it exceeded 8 dB.

When the first legal sound insulation requirements appeared more than 50 years ago, the frequency range of 100 to 3150 Hz became the “traditional” frequency range for European building acoustical requirements, field tests, and laboratory tests. However, in countries with lightweight building practice, for example, Sweden and Norway, the need to include lower frequencies (<100 Hz) gradually became obvious.

Influenced by the French concepts R_{rose} and R_{route} and the increasing need in other countries for evaluation of traffic noise insulation and for including low frequencies (down to 50 Hz), ISO 717:1982 was revised thoroughly. The next (and most recent) version of ISO 717:1996⁹ includes a range of spectrum adaptation terms for rating of sound insulation. As a consequence, the standard opens up the possibility to apply these adaptation terms for an extended frequency range down to 50 Hz by adding such terms when specifying the requirements for sound insulation. In parallel, ISO 140 was updated, the field parts being published in 1998; see Ref. 8. The ISO 140 standards and ISO 717 standards have also been published as European standards (EN ISO). An overview of the ISO 717 history is found in Table 1.

The current international concepts for evaluation of airborne and impact sound insulation are defined in ISO 717-1⁹ and ISO 717-2,⁹ respectively. In Table 2 an overview is found of the basic ISO 717 concepts (single-number quantities) and the spectrum adaptation terms intended for specification and test of:

- Airborne sound insulation between dwellings
- Airborne sound insulation for facades
- Impact sound insulation between dwellings

The spectrum adaptation terms have been introduced to take into account different spectra of noise sources: C and C_{tr} (corresponding to pink noise and road traffic noise, respectively) for airborne sound insulation (see Table 3) and C_1 ($L'_{n,w} + C_1 + 15$ corresponds to the energy sum) for impact sound insulation. The spectrum adaptation terms—colloquially named C corrections—may be calculated for the usual frequency range or for an enlarged frequency range including the one-third octave frequency bands 50, 63, and 80 Hz (C , C_{tr} , C_1) and/or 4000 and 5000 Hz (C and C_{tr} only). The octave band measurement results may be used for rating field measurements. The C corrections are equipped with indices specifying the type of spectrum and the frequency range, if enlarged (see Table 2). The maximum unfavorable deviation shall no longer be indicated, even if it exceeds 8 dB. However, the C corrections are more restrictive to dips and peaks in the airborne and impact sound insulation curves, respectively, thereby to some extent substituting for the former 8-dB rule.

The single-number quantities and the spectrum adaptation terms are derived from one-third octave values (laboratory and field) or 1/1 octave values (field only) measured according to ISO 140.⁸ The

different adaptation terms will enable one to take into account different types of noise spectra, without leaving the well-known reference curve system. Thus, C , C_{tr} , and C_1 have not been included directly in any single-number quantities but have been introduced as separate terms to be added. In Table 2 the “one-third octave” ISO 717 single-number field quantities, spectrum adaptation terms, and the total number of concepts are indicated.

A requirement may be expressed as the sum of a single-number quantity and a spectrum adaptation term or solely as the single-number quantity. Consider examples on statements of airborne and impact sound insulation requirements:

$$\begin{aligned} D_{nT,w} &\geq 55 \text{ dB} & L'_{nT,w} &\leq 50 \text{ dB} \\ D_{nT,w} + C &\geq 55 \text{ dB} & L'_{nT,w} + C_1 &\leq 50 \text{ dB} \\ D_{nT,w} + C_{50-3150} &\geq 55 \text{ dB} & L'_{nT,w} + C_{1,50-2500} &\leq 50 \text{ dB} \end{aligned}$$

In 2004 a survey describing the main sound insulation requirements between dwellings was carried out in 24 countries in Europe.⁵ A comparison of requirements revealed considerable differences, not only in level of requirements but also in terms of descriptors used and the frequency range applied. In the lower part of Table 2—based on the 2004 survey⁵—information has been added about the number of concepts actually applied in Europe. Table 2 also indicates the number of countries applying spectrum adaptation terms (including low-frequency terms). The results of the European survey are described in Sections 4 and 5. In Section 6 are found the basic single-number quantities for field use, the terms they are derived from as well as equations, and references to definitions in the relevant standards. Building codes in the United States are covered in Chapter 113.

All ISO standards mentioned in this chapter are also EN standards and thus implemented in the CEN member countries. Although implemented in all CEN countries, ISO 717 field concepts are not necessarily applied in all national building regulations, for example, national concepts $I_{w,k}$ and I_{co} are applied in the Netherlands; compare Section 4. Only products subject to free trade must apply concepts defined in the harmonized standards.

The above considerations concern concepts as defined in ISO 717. The United States and Canada use American Society for Testing and Materials (ASTM) standards, defining slightly different single-number quantities and no spectrum adaptation terms. For airborne sound the ASTM method differs in two main aspects: Frequency range of 125–4000 Hz and the 8-dB rule is included. The ASTM rating procedure for impact sound insulation is also similar to the ISO procedure, but again ASTM applies the 8-dB rule. For further information about the ASTM impact sound ratings, see Refs. 14 and 15. Japan has partly incorporated ISO standards in the Japanese standards, but they are seldom used in the field, see Ref. 16 for an overview of building acoustical standards in Japan.

^aIn several European countries calculation models for highway road noise and railway noise exist, which define octave band levels; these could be used for comparison with spectra 1 and 2.^bThe spectra 1 and 2 are defined in ISO 717-1.Source: Table A.1 from ISO 717-1 : 1996.⁹

4 BUILDING CODES IN EUROPE

Building codes include typically acoustical requirements concerning:

- Airborne sound insulation between dwellings
- Impact sound insulation between dwellings
- Facade sound insulation (or indoor noise levels from traffic and industry)
- Noise from building services and equipment

In addition, there may be other requirements. Examples are limits concerning vibration levels and reverberation time. This chapter mainly deals with the main requirements related to airborne and impact sound insulation. For facades only qualitative overview information is included.

To ensure that completed buildings fulfill the requirements, detailed designs may be carried out applying prediction methods, for example, EN 12354,¹⁷ based on the performance of the building elements (direct transmission) and junctions (flanking transmission). The performance data may be determined by calculations (applying construction and material characteristics) or by laboratory measurements carried out according to ISO 140⁸ (direct transmission) and ISO 10848¹⁸ (flanking transmission). An overview of the principles of the prediction methods is found in Ref. 19.

The main requirements on airborne sound insulation between dwellings in the 24 European countries responding in the 2004 survey⁵ are presented in Table 4. Similarly, the main requirements on impact sound insulation are presented in Table 5. In several countries the sound insulation requirements were originally based on the actual performance of traditional building constructions that were considered to offer a sufficient level of sound insulation; see Section 3. An exception is Austria, where the requirements²⁰ were based directly on a large survey in 1974²¹; the strictest requirements in the world are probably found in Austria.

The requirements in Tables 4 and 5 cannot be compared without being converted to the same concept. However, a correct conversion depends on the actual conditions for room dimensions, partition area, and other conditions and the conversion of values between different concepts is highly uncertain, especially when “low-frequency” spectrum adaptation terms—including C_{tr} —are involved. Based on previous experience, a rough conversion has been presented in Ref. 4, although the conditions for the conversion are no longer valid due to changes in building practice.

A comparison of requirements revealed considerable differences, not only in level of requirements but also in terms of descriptors used and the frequency range applied. Ten different concepts were applied for airborne and six for impact sound insulation requirements, not counting variants and additional recommendations. Significant differences are found when comparing sound insulation requirements in different countries:

Airborne Sound Insulation	Impact Sound Insulation
10 concepts + variants/recommendations	6 concepts + variants/recommendations
For multistory housing variation > 5 dB	For multistory housing variation > 15 dB
For terraced housing variation > 10 dB	For terraced housing variation > 15 dB
The strictest requirements are found in Austria	The strictest requirements are found in Austria

The total number of concepts applied is found in Table 2. The most recent version of the standard ISO 717⁹ has contributed to the diversity by allowing different concepts and by introducing spectrum adaptation terms with different—extended—frequency ranges for the evaluation. In addition, national, special rules have been added in some countries to compensate for shortcomings or difficulties of field test procedures and conditions.

During the last decade low-frequency descriptors have been introduced in all five Nordic countries and in Lithuania. The low-frequency terms are included in the legal minimum requirements in Sweden (see Tables 4 and 5) and in the criteria for the higher, voluntary quality classes in classification schemes in all six countries, see Section 5.

In building acoustics, the frequency range has traditionally been 100 to 3150 Hz. However, a trend toward lightweight building constructions has increased the low-frequency problems, for example, due to neighbors’ music and footfall noise. Thus, a growing need to include the low-frequency sound insulation has been recognized. In general, there seems to be a trend toward increasing the requirements and including the spectrum adaptation terms in the concepts defining the airborne and impact sound insulation requirements, although the process is slow.

In 2003 the United Kingdom took a step in a different direction than other countries by introducing the spectrum adaptation term C_{tr} as a part of the required criterion for airborne sound insulation between dwellings in general, although C_{tr} is based on an average traffic noise spectrum and has a strong weight at low frequencies. The “ C_{tr} spectrum” is intended for optimizing sound insulation against traffic and other sources with significant low-frequency contents, for example, disco music. The idea behind including C_{tr} for evaluation of sound insulation between dwellings is to take into account low frequencies without actually having to design for or test at low frequencies (assuming that if a construction gives good sound insulation down to 100 Hz, the sound insulation below 100 Hz is probably also good). The idea is interesting, but apart from the conference paper,²² there seems to be no official reports or articles available justifying that this is a cost-effective and balanced way to meet the needs for increased sound insulation in an

remained essentially unchanged in several countries, although neighbor noise levels and the demand for comfort have increased. There may be several reasons for being reluctant to change requirements, one of them being the fear of economic consequences, another

being the difficulties with update of guidelines without extensive experience. In spite of this, stricter requirements have been implemented or proposed in some countries during the last few years, but it is a very slow process for the above-mentioned reasons. However, sound classification schemes can partly compensate for lack of appropriate legal requirements and at the same time provide different quality levels; see Section 5.

Legal requirements concerning sound insulation against traffic noise differ even more than requirements for sound insulation between dwellings due to not only different concepts but also different principles. There is a variety of ways to express facade sound insulation requirements. Several countries specify the required sound insulation of facades as a function of the outdoor noise level (often in quite rough 5-dB steps), sometimes with different day and night requirements. Other countries require the indoor level $L_{A,eq,24h}$ to be below a certain limit, and there may be additional maximum limits for "events." In addition, the methods for determination of the exterior noise exposure vary considerably. In some countries there are no general, national legal sound insulation requirements, but only local. In total, the situation is quite complex. On a European level the Environmental Noise Directive 2002/49/EC (often abbreviated END)² defines two main indicators, L_{den} and L_{night} for description of annoyance and sleep disturbance, respectively, to be introduced in EU member states and to be applied for mapping. Future criteria for facades might be expected to be expressed by these harmonized environmental noise indicators. Noise mapping and actions are required according to the time schedule in the END.² The main purpose is to reduce noise exposure to a more reasonable level outdoor as well as indoor. The primary goal is to reduce outdoor noise levels by reducing emission from vehicles (road, railway, air, construction equipment) and to increase facade sound insulation, where necessary to obtain satisfactory conditions for the inhabitants. The activities are described in several publications, see, for example, Ref. 7.

For years, there have been discussions about the sufficiency or insufficiency of the ISO tapping machine, and alternative sources, for example, rubber balls, have been proposed. However, it seems as if the main problem might be that the low-frequency energy actually produced by the tapping machine is ignored in

most countries.⁴ Sweden is the only country applying $C_{1,50-2500}$ for legal requirements; see also Table 5.

To gather information and share experience more systematically about sound insulation requirements, a working group, EAA TC-RBA WG4,²⁴ has been established under the European Acoustical Association (EAA), Technical Committee Room and Building Acoustics (TC-RBA) aiming at recommendations for harmonization of concepts applied for sound insulation requirements.

5 CLASSIFICATION SCHEMES IN EUROPE

Acoustical classification schemes exist in nine countries in Europe. France and Germany were the first countries to prepare and publish such schemes. An overview of European classification schemes is found in Table 6. The main criteria for airborne and impact sound insulation between dwellings are found in Tables 7 and 8. Criteria for sound insulation internally in dwellings are found in Tables 9 and 10. Facade sound insulation criteria are described in Ref. 25. The schemes include several other criteria concerning sound insulation and noise levels. For complete information, see the standards.²⁶⁻³⁴

For lightweight buildings it is important that low-frequency spectrum adaptation terms (down to 50 Hz) according to ISO 717⁹ are included, implying a significantly improved correlation between subjective and objective sound insulation; see Ref. 35. The low-frequency descriptors have been introduced in all five Nordic countries and in Lithuania, but in no other countries. The low-frequency terms are included in the legal minimum requirements in Sweden and in the criteria for the higher, voluntary quality classes in the classification schemes in all six countries. The importance of including low frequencies for impact sound is also emphasized in Refs. 4, 14, 15, and 36. The Nordic schemes are based on a common Nordic draft,³⁷ following several investigations.³⁸⁻⁴⁰ A list of all European schemes is found in Table 6.

The different classes in classification schemes are intended to reflect different levels of acoustical comfort. Taking into account also economical factors, different classes in the same scheme may apply different concepts as in the five Nordic countries and Lithuania.

^aConditions vary. Typically at least one (sleeping) room shall fulfill the conditions.

Concerning sound insulation against traffic noise, the schemes in Norway, Denmark, and Iceland specify maximum indoor level $L_{A,eq,24h}$ 20, 25, 30, and 35, and dB for classes A, B, C, and D (class C equals legal requirements). Sweden has slightly different criteria. The upper class seems to be quite strict and may not be realistic. The German schemes (and legislation) apply a different approach. The sound insulation of

the facade is specified as a function of the outdoor level, and classes I and II refer both to the same legal requirements, while class III specifies +5 dB higher sound insulation. Future criteria for facades might be expressed by the harmonized environmental noise indicators L_{den} and L_{night} for description of annoyance and sleep disturbance, respectively, see definitions in Ref. 2.

As an alternative or supplement to extensive classification schemes, some countries have defined a simple set of criteria for specification of increased acoustical comfort, for example, added in an Annex in the document describing the legal requirements. Such criteria are found in for example, Austria²⁰ and Germany.⁴¹ The Austrian criteria²⁰ are described as improvements in decibels compared to the legal minimum requirements: (1) For airborne sound insulation between dwellings and for airborne sound insulation of facades, an improvement of 3 dB is defined; (2) for impact sound insulation between dwellings, an improvement of 5 dB is required; and (3) noise levels from technical installations shall be reduced by 5 dB.

Considering the classification schemes in Europe there are several discrepancies:

- Concepts used for description of sound insulation and noise criteria
- Number of quality classes and intervals between classes
- Use of low-frequency spectrum adaptation terms according to ISO 717:1996⁹
- Sound insulation internally in dwellings
- Common or separate quality levels for multi-story and terraced housing
- Balance between criteria for airborne and impact sound insulation
- Relation to legal requirements

The status of the classification schemes in relation to the legal requirements varies. In some countries the building code and the classification standard are incoherent. In other countries they are strongly “integrated,” implying that the building code refers to a specific class in the classification standard rather than describing the requirements. In Finland, Norway, Sweden, and Lithuania, class C equals the legal

Table 11 Airborne Sound Insulation between Rooms – Definitions of Field Properties according to ISO 140-4

Weighted Value	Equations ^a for 1/3 or 1/1 Octave Values	Explanations of Symbols
R'_w	(6) $R' = L_1 - L_2 + 10 \log(S/A)$ dB	L_1 is the average SPL in the source room.
$D_{n,w}$	(3) $D_n = L_1 - L_2 - 10 \log(A/A_0)$ dB	L_2 is the average SPL in the receiving room.
$D_{nT,w}$	(4) $D_{nT} = L_1 - L_2 + 10 \log(T/T_0)$ dB	S is the area of the separating element. A is the equivalent sound absorption area in the receiving room. A_0 is the reference absorption area, in square metres; $A_0 = 10 \text{ m}^2$. T is the reverberation time in the receiving room. T_0 is the reference reverberation time; for dwellings, $T_0 = 0.5 \text{ s}$. $A = 0.16V/T$, where V is the room volume.

^a Definitions and equation numbers refer to ISO 140-4:1998.⁸

Table 12 Airborne Sound Insulation of Facades – Definitions of Field Properties according to ISO 140-5^a

Weighted Value	Equations ^a for 1/3 or 1/1 Octave Values	Explanations of Symbols ^b
$R'_{45^\circ,w}$	(3) $R'_{45^\circ} = L_{1,s} - L_2 + 10 \log(S/A) - 1.5$ dB	$L_{1,s}$ is the average SPL on the surface of the test specimen.
$R'_{tr,s,w}$	(4) $R'_{tr,s} = L_{eq,1,s} - L_{eq,2} + 10 \log(S/A) - 3$ dB	L_2 is the average SPL in the receiving room.
$D_{ls,2m,n,w}^c$	(7) $D_{2m,n} = L_{1,2m} - L_2 - 10 \log(A/A_0)$ dB	$L_{eq,1,s}$ is the average value of the equivalent continuous SPL on the surface of the test specimen including reflecting effects from the test.
$D_{ls,2m,nT,w}^a$	(6) $D_{2m,nT} = L_{1,2m} - L_2 + 10 \log(T/T_0)$ dB	$L_{eq,2}$ is the average value of the equivalent continuous sound pressure level in the receiving room $L_{1,2m}$ is the outdoor SPL 2 m in front of the façade. S is the area of the test specimen, determined as given in annex A.

^a Definitions and equation numbers refer to ISO 140-5:1998.⁸

^b For explanation of A , A_0 , T , T_0 , $A = 0.16V/T$, see Table 11.

^c ISO 140-5, Table 1, has an overview of different measurement methods corresponding to different sound sources (loudspeakers as well as road, railway, and air traffic). Guidelines for positioning of loudspeakers and outdoor microphones are also found in ISO 140-5. If traffic is applied as source, the “ls” in the index should be replaced by “tr”.

Table 13 Impact Sound Insulation between Rooms – Definitions of Field Properties according to ISO 140-7

Weighted Value	Equations ^a for 1/3 or 1/1 Octave Band	Explanations of Symbols ^b
$L'_{n,w}$	(2) $L'_n = L_i + 10 \log(A/A_0)$ dB	Impact sound pressure level, L_i , is the average SPL in the receiving room when the floor under test is excited by the standardized impact source; it is expressed in decibels.
$L'_{nT,w}$	(3) $L'_{nT} = L_i - 10 \log(T/T_0)$ dB	

^a Definitions and equation numbers refer to ISO 140-7:1998.⁸

^b For explanation of A , A_0 , T , T_0 , $A = 0.16V/T$, see Table 11.

requirements, and classes A and B define higher levels of acoustical comfort. As a consequence, attention is drawn to the fact that the legislative requirements are minimum requirements, providing a possibility to voluntarily specify and design for a better acoustical quality.

6 FIELD MEASUREMENTS – CHECK OF COMPLIANCE WITH CRITERIA

A check for compliance with requirements may be made by carrying out field tests in the finished building. The equations to be applied, when testing sound insulation in buildings, are found in Tables 11, 12, and 13 for airborne sound insulation between dwellings, for facade sound insulation, and for impact sound insulation between dwellings, respectively. The evaluation concepts are found in the left columns in the tables. Names of properties and corresponding single-number quantities are described in Table 14.

The property to be measured in a specific situation is specified in the legal requirements or by the builder. The test results are to be compared with the limits, and the test methods are defined in the standards. Thus, it should be simple. However, in practice there are several precautions to take to ensure reliable sound insulation measurement results. Examples on questions and situations relate to among other things the shapes of the rooms, for example, irregular, long, narrow, staggered, partly divided, extremely complicated room geometry, big differences in room volume, and to microphone and source positions. Concerning facade sound insulation measurements, there are some additional questions about the type of source (traffic or loudspeaker). If a loudspeaker is used, which position should it be used in, how should it be arranged, and so forth.

Due to severe difficulties in the field, a whole set of guidelines have been made and published in ISO 140-14, which is to be applied in combination with ISO 140-4 and ISO 140-7. ISO 140-14 has five Annexes with guidelines aiming at more reliable measurements according to ISO 140-4 and ISO 140-7.

The extent of the guidelines indicates how important it is to choose concepts for building regulations that reduce the difficulties as much as possible, of course, also taking into account the importance

Table 14 Names of Sound Insulation Field Properties Listed in Tables 11–13

Term ^a	Symbol ^b	Definition
Apparent sound reduction index	R'	Table 11
Normalized level difference	D_n	Table 11
Standardized level difference	D_{nT}	Table 11

Normalized level difference	$D_{2m,n}^c$	Table 12
Standardized level difference	$D_{2m,nT}^c$	Table 12
Normalized impact sound pressure level	L'_n	Table 13
Standardized impact sound pressure level	L'_{nT}	Table 13

^a The corresponding single-number quantity has the same names with “Weighted” added in front of the term indicated; see also ISO 717.

^b The corresponding single-number quantity has the same symbol with “w” added in the end of the index, see ISO 717.

^c The index has a prefix “tr” or “ls” dependent on whether the sound source is traffic or a loudspeaker.

of correlation with subjective evaluation. Thus, it is important that the properties applied are well defined (i.e., all parts of the basic equation should exist) and that the results are reproducible, that is, the measurement uncertainty should be low, so it is easy to determine compliance with requirements. The goal for concepts must be a high correlation between prediction, measurement results, and subjective evaluation. This subject is further elaborated in Ref. 6.

7 SUMMARY

After approximately 50 years with almost no changes in building acoustical requirements in Europe, there is a trend toward stricter requirements, although the process is slow. During the last decade voluntary classification schemes describing different levels of acoustical comfort have been introduced in nine

countries in Europe, thus covering the need to define different quality levels.

A comparison between 24 European countries of the legal requirements for sound insulation between dwellings reveals significant differences concerning concepts as well as levels, and the requirements for facades differ even more. None of the voluntary classification schemes are identical.

The most recent version of standard ISO 717⁹ has contributed to the diversity by allowing different concepts and by introducing spectrum adaptation terms with different—extended—frequency ranges toward lower and higher frequencies for the evaluation. In addition, national, special rules have been added in some countries to compensate for shortcomings or difficulties of field test procedures and conditions.

The findings do not reflect a harmonized Europe. In the future, efforts should be made to increase the harmonization of concepts (not necessarily levels), and the requirements for facades should be based on the harmonized environmental noise indicators L_{den} and L_{night} (see Ref. 2) for description of annoyance and sleep disturbance, respectively.

To gather information and share experiences more systematically about sound insulation requirements, a working group, EAA TC-RBA WG4,²⁴ has been established under the European Acoustical Association (EAA), Technical Committee Room and Building Acoustics (TC-RBA) aiming at recommendations for harmonization of concepts applied for sound insulation requirements.

More noise sources—including neighbors' activities—and an increased demand for high quality and comfort together with a trend toward lightweight constructions are contradictory and call for optimizing building design using acoustical prediction models; see Ref. 19.

The benefits of a harmonization include facilitating the exchange of information and experience and development of design tools. Based on the experience, legal requirements and classification criteria might be adjusted and optimized.

Acknowledgments The author is grateful to all the people who provided information about national sound insulation requirements and classification schemes. I hope that the data have been correctly understood and described. Any corrections or updates of information will be appreciated.

CHAPTER 115

NOISE IN COMMERCIAL AND PUBLIC BUILDINGS AND OFFICES – PREDICTION AND CONTROL

Chris Field

Arup Acoustics San Francisco
San Francisco, California

Fergus Fricke

School of Architecture
University of Sydney
Sydney, New South Wales, Australia

1 INTRODUCTION

Commercial and public buildings such as offices, malls, stores, motels, hospitals, schools, universities, airport terminals, law courts, police stations, libraries, museums, and churches all have the potential to be seriously effected by noise. These buildings represent a very diverse group. Although some buildings may require special noise control considerations, for most of these buildings, it is possible to set down a general approach to noise control by considering noise criterion, noise sources (such as transportation and mechanical services), and noise control techniques. The most common techniques include consideration of transmission of sound through walls and floors, vibration isolation, and sound absorption in the rooms. A commonly used method of designing for noise in commercial and public buildings is given, based on tabulated data of planning noise criteria, interior sound sources, measurements or estimates of exterior noise, and the acoustical properties of materials and constructions. In some special buildings, such as concert halls, a more sophisticated approach to noise control must be used and noise issues considered at an early stage in the design.

2 GENERAL APPROACH TO NOISE CONTROL IN BUILDINGS

Noise control in commercial and public buildings usually involves consideration of the effect of sound transmission from interior and exterior sources and the reverberation of sound in occupied spaces, on speech privacy, speech intelligibility, and annoyance. In some cases, issues of concentration on tasks, sleep, and even health and social behavior may also need to be considered. The interior noises of concern may be air-conditioning systems, office equipment such as computers and copiers, conversations, or coffee makers. The external sound sources are usually associated with roads, rail traffic, aircraft, building or mechanical services involving pumps

or fans but not building construction, and other temporary or intermittent activities such as lawn mowing. The acoustical design of a building may also involve the impact, on neighboring buildings, of noise generated in or by the building being designed.

Design for noise in buildings can be considered under the usual three categories of source(s), path(s), and receiver(s). Where external noise sources are concerned, there is no opportunity for controlling noise at the source and very little opportunity for controlling noise at the receiver, and so noise control is predominantly by the building fabric. Building siting is important as noise problems can be caused to, as well as from, the local environment. For internal noise sources there is some possibility of source noise control, by the selection of mechanical plant, for instance, but again the control of noise is predominantly by the building fabric and the layout of the building (where sensitive and noisy spaces are located).

The approach to noise control then amounts to the determination of potential sound pressure levels from interior and exterior noise sources, the selection of appropriate noise criteria for the activities to be carried out in spaces in the building, and the design of the layout of the building and specification of materials, construction, and finishes in the building. One acoustical design approach is to estimate or measure the peak sound pressure levels at the building site and design the external envelope to reduce these to A-weighted levels about 5 dB below the background noise level caused by the air-conditioning system or the sound system designed to produce masking noise.

In the design procedure presented here, single-number criteria, sound pressure levels, and properties of materials and constructions are used. A frequency-dependent approach, such as in the music and media facilities, for instance, is beyond the scope of this chapter but is addressed in other texts, as are other design procedures.^{1–4}

3 PLANNING NOISE CRITERIA

The siting of a building can be as important for producing a satisfactory sound environment (both inside and outside a building) as the design of the building itself. Whether this needs to be considered depends on the existing (and potential future) external noise sources, the sensitivity of the occupants, the activities in the building, and the budget for the building. It is always possible to design and construct buildings such as airport terminals and airport hotels for very noisy environments, but noise control comes at a price that tends to increase exponentially with the degree of noise control. It should be understood though that while it is possible to achieve a satisfactory internal sound environment in a building near a major airport or highway, this is unlikely if the building is to be naturally ventilated.

Often the most effective way of dealing with external noise is by way of site selection. In some countries there are standards and codes regulating or giving recommendations for the siting (and construction) of buildings in relation to major transportation noise sources.^{5,6} Noise-sensitive buildings such as schools should generally not be sited on busy roads or under flight paths. Likewise, rooms that are noise sensitive should not be located near rooms in which the sound pressure level is expected to be high. For example, a plant room located directly above a CEO's office is not good planning.

There are many different planning criteria worldwide, and so it is difficult to give general coverage to this aspect of planning for noise and noise control. Here we give some recommended planning noise levels for Denmark⁷ as it has some of the most stringent recommendations. In general Denmark follows World Health Organization and the Organization of Economic Cooperation and Development recommendations^{8,9} and avoids using source-specific noise metrics. The Danish planning levels are of particular interest because they address the issue of different sound sources, of the times of occurrence of the noise, the character of the noise (low-frequency content and tonal and impulse corrections for some sources), and peak sound and vibration levels. Examples of the planning levels, which are not mandatory, are summarized in Table 1 for commercial and public buildings. Such criteria usually refer to sound pressure levels 1.2 m above the ground at the boundary of the nearest property and at least 2 m away from a building facade.

4 BUILDING NOISE CRITERIA

One of the most interesting aspects of designing buildings is the difficulty in dealing with multiple requirements that may be contradictory. Developing noise criteria is no exception and cannot be treated in isolation. For example, there is little point in specifying double glazing to control external noise if windows need to open for ventilation.

Theoretically (simplistically), it should only be necessary to set criteria based on acceptable internal sound pressure levels in spaces for the activities being

carried out in the building. In practice, it is usually necessary to specify the sound isolation performance of common walls between spaces, for example, the sound transmission class (STC), or weighted sound reduction index (R_w) value of walls separating motel rooms, as well as reverberation times. The STC (R_w) values are set because it is not possible to estimate what sound sources will be present in a building during its life, and, like other aspects of the environment, buildings can only be expected to moderate the external environmental conditions, such as noise events, rather than to produce constant sound pressure levels. Reverberation time is important for aural comfort as well as controlling sound pressure levels.

Much of the material on recommended sound levels in buildings has been developed over many years and should be considered as a mixture of practical and idealistic criteria. The interior sound pressure levels specified in Table 2 are for unoccupied spaces with air-conditioning and other services operating. The levels are assumed to be approximately steady, and so there is no need to specify a noise metric that accounts for temporal variations in the noise. For temporal variations of less than ± 3 dB an arithmetic average level can be assumed. For greater variations in level a metric such as L_{Aeq} should be used, but existing interior noise criteria should be considered as suitable for quasi-steady-state situations. There are other noise metrics used, for example, balanced noise criterion (NCB) and room criteria (RC)^{10,11} besides the two common ones, noise criterion (NC) and L_{Aeq} , in Table 2. There are more comprehensive tabulations of indoor noise criteria.^{12,13} Typical values of recommended sound isolation performances of walls in office buildings are given in Table 3.

There can be too little noise as well as too much noise, although this is rare. If the sound pressure levels in a building are too low, then minor activity noise can be disruptive and speech privacy cannot be achieved with economically viable constructions. If external sound pressure levels are low and a building is naturally ventilated, then again it may be difficult/expensive to achieve satisfactory speech privacy between workstations in open-plan offices or to control noise from the building affecting neighbors, for example, a school next to residential buildings.

An office building containing open-plan offices with many workstations is a special case where a compromise on background noise, screen, or partial-height partition attenuation values, speech level, and reverberation time must be considered to achieve adequate speech privacy and adequate speech intelligibility within a workspace (see also Chapter 109).

5 NOISE SOURCES

The noise sources that should be considered in commercial and public buildings can be considered in two categories: external and internal.

The major external noise sources are usually concerned with transportation: road traffic, aircraft, trains, and, occasionally, shipping. However, there are many other sources that may be significant at a given site.

Table 1 Partial Summary of Danish Recommended Planning Sound Pressure Levels

a. Noise Limits from Commercial and Industrial Enterprises^a			
Building location and use	Mon–Fri, 7 a.m.–6 p.m., Sat, 7 a.m.–2 p.m.	Mon–Fri, 6–10 p.m., Sat, 2–10 p.m., Sun and public holidays, 7 a.m.–10 p.m.	All days, 10 p.m.–7 a.m.
Commercial and industrial areas	70 dB	70 dB	70 dB
Mixed residential/commercial areas, urban centers	55 dB	45 dB	40 dB
b. Recommended Limit Values for Use When the Enterprise and the Dwelling Are Located in the Same Building^b			
	Day and evening, 7 a.m.–10 p.m.		Night, 10 p.m.–7 a.m.
Enterprises, apart from offices	50 dB		50 dB
Offices	40 dB		40 dB
Rooms in dwellings	30 dB		25 dB
c. Recommended Road Traffic Noise Limits^c			
Public institutions (hospitals, educational institutions, schools): 55 dB			
Service enterprises, (hotels, offices, etc.): 60 dB			
d. Recommended Train Noise Limits^d			
Public institutions (hospitals, schools, etc.): 60 dB			
Service enterprises (hotels, offices, etc.): 65 dB			
e. Recommended Aircraft Noise Limits^e			
Residential areas and noise-sensitive public institutions (schools, hospitals, nursing homes, etc.): 55 dB			
Service enterprises (hotels, offices, etc.): 60 dB			

^aThe noise limits in part (a) are A-weighted equivalent sound pressure levels (L_{Aeq}), i.e., the energy averaged value over a specified period (8 h during the day, 1 h in the evening, and one-half hour at night). If the noise contains clearly audible tones or impulses, 5 dB must be added to the equivalent noise level to determine the noise rating level. The recommended noise limits refer to outdoor sound pressure levels.

^bThe recommended limit values in part (b), for noise from an enterprise, are indoor A-weighted equivalent sound pressure levels (L_{Aeq}).

^cOutdoor recommended limits in part (c) are 24-h L_{Aeq} values.

^dThe limits specified in part (d) are outdoor 24-h L_{Aeq} values. There are also requirements governing both the maximum sound and vibration levels at individual dwellings. The recommended maximum limit value is an A-weighted sound pressure level of 85 dB. To avoid vibrations, minimum planning distances have been laid down for the distance from a building to the center of the tracks.

^eThe recommendations quoted in part (e) are A-weighted equivalent sound pressure levels over a 24-h period (L_{Aeq}), where 5 dB has been added to the sound pressure levels in the evening period (7–10 p.m.) and 10 dB to the sound pressure levels at night (10 p.m.–7 a.m.) for commercial and military aircraft.

Source: From Ref. 7.

Table 2 Examples of Approximate Recommended Sound Pressure Levels (Unoccupied) and Reverberation Times^a

Room	A-weighted	NC	RT (s)
Private office	40	35	0.5
General office	45	40	0.5
Courtroom	40	35	0.8
Churches	35	30	1.0
Hospital ward	35	30	0.5
Hotel/motel bedroom	35	30	0.5
Restaurants	45	40	<1.0
Classroom/conference room	35	30	0.7

^aAppropriate values in this table may depend on room size, amplification, and other factors.

Noise from industrial sites as well as sporting and cultural activities are occasionally significant. For schools the external sounds of children playing may be noise for classrooms. In public and commercial buildings noise sources such as fans and chillers in adjacent buildings and utilities such as transformers, sewage, and water pumps can be of concern, but these sources are usually controlled under environmental protection legislation. Construction site noise and alarms on buildings and vehicles can also be annoying sources, but these are infrequent events and are not designed for.

The major noise sources inside buildings besides people activity noises, such as conversations, footsteps, doors closing, sound systems, and music, are the heating, air-conditioning, and ventilation systems used.

Table 3 Examples of Recommended Laboratory Measured STC (R_w) Values to Achieve Adequate Sound Pressure Levels and Speech Privacy^a

Room	Adjacent Room	STC (R_w) Value of Common Wall/Floor
General office	Corridor/lobby	45
	Plant room	60
Conference room	Conference room	50
	Office	50
	Toilet	55
	Plant room	60
Private office	Private office	50
	General office	45
	Corridor/lobby	50

^a(These should be considered as approximate as published recommendations vary by about \pm STC 5 from the values listed in table.)

Other building services, such as lifts and plumbing, can also be important. External sound pressure levels can be measured at a site or can be estimated based on traffic usage of nearby roads, railroads, or aircraft flight paths, although whether these sound pressure levels will be maintained over the lifetime of the building is dubious.

5.1 Road Noise

There are many procedures for the estimation of road traffic noise^{14,15} (see also Chapter 120) and recommendations for location of buildings based on noise metrics such as L_{A10} and L_{Aeq} . These methods take account of the vehicle flow rates, the mix of light and heavy vehicles, the speed of vehicles, whether the vehicles are freely flowing or not, the road gradient, the road surface, the topography of the surroundings, the distance to the road from the site under consideration, and the presence of roadside barriers or other buildings. Obviously, the noise will also depend on the make and model of vehicles and how well the vehicles are maintained.

An approximate estimate of the L_{Aeq} from a road over flat ground can be obtained from

$$L_{Aeq} = 55 + 10 \log(Q) + 0.3p - 20 \log(d) \quad \text{dB}$$

where Q is the vehicle flow rate in vehicles per hour, p is the percentage of heavy vehicles, and d is the distance in metres from the center of the nearside traffic flow. To achieve a value of L_{Aeq} of 55 dB with a traffic flow of 1000 vehicles per hour and 10% heavy vehicles would require a distance of approximately 50 m from the road.

5.2 Aircraft Noise

There are a bewildering number of aircraft noise metrics [e.g., maximum overpass sound pressure level (L_{max}), noise and number index (NNI), noise exposure forecast (NEF), Australian noise exposure forecast (ANEF), and time above A-weighted sound pressure

level of 70 dB (TA70)] and an even larger number of aircraft types, movements, loadings, flight paths, weather conditions and other factors that can affect the sound pressure levels at a building site (see also Chapter 125). It is not possible to give approximate estimates of sound pressure levels experienced near airports, but data on at least one noise metric are often available from aviation authorities for specific airports and military airfields. This is in the form of noise contours, often averaged over a year. Approximate maximum sound pressure levels at a site can be estimated from the maximum pressure level of large commercial aircraft measured during takeoff: approximate A-weighted noise level of 110 dB at 150 m. For most commercial buildings aircraft noise should not be a problem if the building is more than 1 km to the side of a flight path. For public buildings this sideline distance may need to be more than 2 km.

5.3 Air-Conditioning Noise Sources and Control

The main noise sources in air-conditioning systems are the fans, chillers, cooling towers, airflows through ducts, grills and diffusers, and flanking transmission through ducts and plenums (see also Chapters 110 and 112). The control of these sources is largely by the appropriate siting and selection of mechanical equipment, silencers, duct sizes, and linings.¹⁶

5.4 Airborne and Structure-Borne Noise and Vibration Transmission in Commercial Buildings

In commercial buildings as in other buildings and structures, there are two basic forms of sound transmission between spaces: airborne and structure-borne or vibration transmission (see also Chapter 105). Airborne sound transmission, as the name suggests, is the transmission of acoustic energy through the air for all or part of its transmission. Structure-borne transmission involves the direct excitation of the structure by a services source such as a fan or pump or by activity in the building such as people walking on floors with hard surfaces or doors closing, or sporting activity such as a bouncing ball or water lapping against the sides of a swimming pool. Such sound transmission may not be noticeable to occupants of the room in which the source is located but can be annoying to occupants in other parts of the building.

The STC ratings of single-leaf walls, such as solid masonry walls, is wholly determined by the surface density of the wall. For a given type of composite construction, for example, gypsum board on metal studs, the STC value is still mainly dependent on the surface density of the wall, but other factors such as the size, spacing and gauge of the studs, the type and thickness of the absorbing material between the studs, and the use of resilient channels (vibration isolation) all influence the performance. Table 4 indicates approximate values of different constructions and more detailed information can be found elsewhere.¹⁷⁻¹⁹

Structure-borne sound transmission is dealt with by specifying the impact isolation class (IIC) of floors, the

vibration isolation required for different types of rotating machinery, its weight, its center of gravity and floor construction and span, and the vibration isolation of supply and waste pipes from the building structure.²⁰

6 FLANKING TRANSMISSION

Transmission of sound that is not via the most direct path or the major dividing element between spaces is known as flanking transmission. Thus, sound that travels via an air-conditioning duct that services two adjacent rooms is considered to be flanking transmission because the direct transmission path (the shortest path) is through the common wall. Sound transmission is more likely to be affected by flanking transmission the greater the acoustic performance of the common wall is. Below STC (R_w) 35 flanking transmission can usually be ignored. Above STC 55 flanking transmission usually dominates transmission due to poor sealing of joints within the wall or between the wall and other building elements such as other walls or the ceiling or in the air gaps around a door or through a suspended ceiling or return-air plenum or because of the chasing of electrical or hydraulic services within a wall.

There is one flanking transmission path that is often significant in commercial buildings: transmission of sound through suspended ceilings from one office to another. This type of transmission is important because office partitions are often built to the suspended ceiling and not the structural slab. This allows flexibility in office layout without the need to relocate services above the suspended ceiling. However, suspended ceilings often have low mass and hence low STC ratings.

A doorway through a high-performance wall is a sure way of degrading the acoustic performance of a wall, as is the use of return-air grills in doors. Operable walls such as folding and sliding doors tend to have poor acoustic performances partially because of the difficulty in sealing them. The fitting of lightweight partitions is also important.²¹

7 EFFECT OF CONSTRUCTION OF WALLS AND FLOORS BETWEEN INHABITED SPACES

Although there are sophisticated theoretical and empirical equations for calculating the transmission of sound through walls and floors, most of the data used for design purposes comes from laboratory tests. Simple theory based on the surface density of a wall is often adequate for single-leaf constructions. For masonry walls it gives STC values within about \pm STC 2, and there is little advantage in achieving greater accuracy because of wall material, construction, and flanking path variability. The simple model for random incidence sound transmission loss (TL) (also known as sound reduction index) is

$$TL(\text{dB}) = 20 \log(fm) - 47$$

where f is the frequency (in Hz) (using $f = 500$ will give an estimate of the STC value) and m is the surface density (in kg/m^2). Double-leaf constructions

and lightweight constructions require more complex analysis.²²

Besides mass and frequency there are three major factors effecting the sound transmission through walls and floors:

- Whether the wall or floor is a single- or multiple-leaf construction
- Whether, in the case of double- or multiple-leaf construction, the wall-floor has sound-absorbing treatment in the cavity
- Whether, in the case of double- or multileaf construction, the wall-floor has structural isolation (e.g., staggered stud wall or floated floor)

There are many possible constructions for walls and windows and as well as combinations of these. For design purposes it is useful to have some examples. These are given in Table 4 for walls and Table 5 for floors with more comprehensive data available elsewhere.¹⁷⁻¹⁹

8 COMPOSITE CONSTRUCTIONS

It is often the case that walls in commercial and public buildings are not uniform in construction because of doors, windows, or vents. In such situations the values in Tables 4 and 5 may also be used to estimate the “effective” (or “apparent,” “composite,” or “resultant”) STC value due to the inclusion of these other elements. The effective STC value, STC_{eff} , of the wall will depend on the relative areas and one-third octave transmission loss (TL) values of the elements (including air gaps) that form the wall. The expression for calculating the effective transmission loss, TL_{eff} , at a given frequency, is given below. It is common practice to use the same expression for calculating the effective STC value of the common wall by substituting STC for TL.

$$TL_{\text{eff}} = 10 \log \left[\sum A_i / \sum (A_i \times 10^{-0.1 TL_i}) \right]$$

where A_i is the area of the i th component of the wall (in m^2) and TL_i is the transmission loss of the i th component.

Example A wall is composed of brick (STC of 50 and area of 10 m^2) and a window (STC of 20 and area of 1 m^2):

$$\begin{aligned} STC_{\text{eff}} &= 10 \log[11/(10 \times 10^{-5} + 1 \times 10^{-2})] \\ &= 10 \log(11 \times 10^2) \\ &= 30 \end{aligned}$$

9 USE OF SOUND-ABSORBING MATERIALS

The use of sound-absorbing materials in buildings is important for speech intelligibility, aural comfort, and controlling sound pressure levels from mechanical services or other sources. (see also Chapter 104) In

absorbing treatments on walls and ceilings are often of limited use for controlling noise is worth considering as such treatments can be an expensive exercise giving little return when a room is carpeted and has other sound-absorbing furnishings.

In most office spaces speech privacy and low sound pressure levels are aimed for, but these two requirements are, to a degree, mutually exclusive. [A quiet space is one in which conversations can be most easily overheard and where there are the greatest distractions. When the A-weighted sound pressure level exceeds 50 dB, the noise increasingly becomes distracting.] Lower sound pressure levels would result if a ceiling with a higher absorption (NRC* value) were used but by how much? In general terms, if the existing amount of absorbing material in a room is A_1 m² sabin ($A_1 = \sum (A_i \times NRC_i)$ where A_i is the area of surface i of absorption NRC_{*i*}) and the absorption is increased to A_2 m² sabin, the reduction in sound pressure level in the reverberant field (there will be no reduction in sound pressure level in the direct field near the source) will be $10 \log (A_2/A_1)$, which, for a doubling of the average NRC value or area of absorbent, results in a 3-dB reduction in the sound pressure level. However, if there is already a carpet or an acoustic ceiling and absorbent furnishings such as upholstered chairs and curtains, it would be difficult to double the amount of absorbing material in the room, and so any change in the sound pressure level will be small. A doubling of the absorption in a room results in the halving of the reverberation time (reverberation time is inversely proportional to the total absorption), which could have a significant influence on the perception of noise in the room.

*NRC is a commonly used single-figure rating system for materials used where speech is of major importance. It is an average absorption coefficient in the speech frequency range. An NRC rating of 0 means the material reflects all the sound and a value of 1 means it absorbs all the sound. NRC values do not tell the complete story. A high NRC value might be achieved even though the material absorbs sound poorly at low frequencies, for instance. In such a case a room would sound "boomy," and low-frequency absorption using panels of resonant absorbers may need to be used. See Table 6 and other references^{23–25} for some examples of materials and their NRC values.

Table 6 Representative Absorption Coefficients of Materials

Material/Construction	NRC ^a
Masonry walls	
Clay brick (glazed or painted)	0.05
Concrete block (coarse)	0.30
Concrete block (painted)	0.05
Masonry plastered	0.05
Marble or glazed tiles	0.00
Sound-absorbing concrete blocks	0.50
Stud walls/panels

>6 mm	0.05
Ceilings	
12-mm gypsum board	0.05
Rigid mineral fibreboard suspended ceiling	0.60
Cellulose sprayed-on absorbent, 16 mm thick	0.55
Furnishings	
Curtains	
10 oz velour, straight	0.15
18 oz velour, 50% full	0.55
Fabric- or vinyl-covered fiberglass wall panels 50 mm thick	0.80
Fabric- or vinyl-covered fiberglass wall panels 100 mm thick	0.95
People	
On medium upholstered seats	0.80
On hard seats	0.55

^aThe NRC values of some of these finishes, e.g., ceiling panels, will depend on the mounting conditions.²⁶

10 SOUND INSULATION AGAINST TRAFFIC AND AIRCRAFT NOISE

Where codes are available for the construction of buildings against road traffic and aircraft noise,^{5,6} they should be referred to. A simple approach is given below, but it should be understood that the acoustic transmission of facades is more complex than this method would suggest. The spectrum, level, and direction of the sound can vary over the facade that will in turn affect the transmitted sound. While most external sound sources are somewhat different in spectrum to speech (for which the STC rating system was developed) and the angle of incidence is not random (random incidence is used for STC determinations), STC values are often used for outdoor–indoor

Table 7 Outdoor–Indoor Transmission Class^a

Source	Room Furnishings ^b	Façade Area as % of Floor Area						
		20	30	40	60	80	100	160
Aircraft	Hard	−1	+1	+2	+4	+5	+6	+8
	Standard	−3	−1	0	+2	+3	+4	+6
	Soft	−5	−3	−2	0	+1	+2	+4
Road	Hard	+1	+3	+4	+6	+7	+8	+10
	Standard	−1	+1	+2	+4	+5	+6	+8
	Soft	−3	−1	0	+2	+3	+4	+6

^aCorrection to be added to the difference between outdoor and indoor sound pressure levels to obtain the required STC for the facade fenestration.

^b“Hard” is typical of a kitchen or bathroom, “standard” is typical of a living room or dining room, and “soft” is typical of a bedroom.

acoustical design purposes. Where a higher level of accuracy is required the outdoor–indoor transmission class (OITC) can be used.²⁷

For outdoor sources such as aircraft and road traffic that have strong low-frequency components, the perceived insulation tends to be less than indicated by STC ratings. Harris²⁸ gives a correction method based on the noise source, facade area, and room furnishings:

$$L_{\text{out}} - L_{\text{in}} = \text{STC}_{\text{eff}} - \text{correction} \quad (\text{see Table 7})$$

where L_{out} is the outside A-weighted sound pressure level, L_{in} is the inside A-weighted sound pressure level (e.g., criteria in Table 2), and STC_{eff} is the STC value of the composite facade (walls, windows, doors, roof, vents, etc.).

Given the uncertainties in sound levels, perception, and other factors, it can be seen from Table 7 that for facade areas about 20 and 50% of the floor area there is little point in using the OITC in other than exceptional circumstances.

There are also alternatives to the previous equation. The most common is

$$L_{\text{out}} - L_{\text{in}} = \text{STC}_{\text{eff}} - 10 \log(S/A) - 6$$

where S is the area of facade through which the sound is transmitted to a room having A m² sabin of absorption.

The effort to control external sound transmission through the exterior envelope of a building is usually concentrated on windows, roofs, doors, and vents as these are the weakest transmission paths with the windows often being more important in commercial and public buildings while roofs may be more important in residential buildings.

11 ANALYTICAL NOISE MODELS

In buildings, because of the limitations on accuracy of sound transmission predictions due to flanking paths, workmanship, angle of incidence of sound,

unknown noise sources and levels, it is rarely necessary to use sophisticated techniques such as statistical energy analysis (SEA) for high-frequency transmission, finite element analysis/boundary element method (FEM/BEM) for low- to mid-frequency transmission, and the Helmholtz method (for the full-frequency range) to design for noise transmission.^{29–32} There are a number of simple empirical and analytical noise models that are useful, but generally buildings are designed using tabulated values of STC, IONR, IIC, and NRC values as indicated above.

CHAPTER 116

VIBRATION RESPONSE OF STRUCTURES TO FLUID FLOW AND WIND

Malcolm J. Crocker

Department of Mechanical Engineering

Auburn University

Auburn, Alabama

1 INTRODUCTION

Structures immersed in a moving fluid experience fluid loading forces. These forces are caused by several physical phenomena. The phenomena may be divided into three main categories: (1) steady incoming flow that impinges on the structure, (2) unsteady incoming flow, and (3) eddies (vortices) that form in the fluctuating wake flowing past the structure. The manner in which a structure responds to the flow forces is governed by several factors, the most important being: (1) its geometrical shape and dimensions; (2) its boundary conditions and rigidity (stiffness) and mass distributions, which govern its fundamental and higher natural frequencies; and (3) its vibration damping. The structures may be divided into two main types: (1) stiff structures that are relatively rigid and that have fundamental bending and torsional frequencies that are above the predominant fluctuation frequencies in the incoming flow and wake eddy formation rates and (2) flexible structures that have fundamental frequencies much lower than or that coincide with the frequencies of the fluctuating forces in the incoming flow and/or wakes from any neighboring structures upstream. Dynamic forces experienced by “rigid” structures can be divided into two main types: (1) longitudinal forces in the flow direction mostly caused by unsteady incoming flow and (2) lateral and torsional forces that are mainly caused by the vortex shedding in the structure’s own wake. Flexible structures can experience additional forces caused by motion of the structure itself in response to the flow forces. Motion of the structure, sometimes caused by aeroelastic effects, can alter the flow and result in self-generating feedback mechanisms known such as galloping, flutter, or vortex-generated motion resulting in increased vortex shedding.

In addition, aeroelastic effects associated with vortex shedding are also important since, when the vortex shedding frequency coincides with an eigenfrequency, feedback motion results in which the vortex-generated motion intensifies the vortex shedding.

2 FLUID FLOWS

There is a considerable body of literature describing the vibration of structures caused by fluid flow. This chapter describes the response of structures to fluid flow forces and in particular the response of buildings, towers, and other structures to forces caused by

wind. The discussion includes reviews of the physical phenomena involved, methods of vibration prediction, human response to the vibration and methods of vibration reduction and control. In addition, references to the literature are provided for further reading, including books on wind effects on structures,^{1–6} book chapters,^{7–9} books of proceedings,^{10–13} design guides,^{14–18} and articles in journals.^{19–50} There are many books covering the dynamic response of structures that are also useful in study of this topic.⁵¹

2.1 Fluid Flow around a Body

When a fluid flow meets a structural body, the flow is perturbed as it travels around the structure. The flow behavior depends on several factors. In practice, the main fluid effects are due to the fluid’s *viscosity* and *inertia*. When a fluid flows near to the surface of a body, its viscosity causes it to adhere to the surface and to slow down near to the surface. The result is that a slowly moving layer of fluid exists near to the surface known as a boundary layer. Figure 1 shows the velocity profile of a typical boundary layer. In pipes and machinery elements containing fluid flow, boundary layers tend to grow in thickness with distance along the surface. In atmospheric wind the boundary layer is more or less constant in thickness, except that it differs in thickness depending upon the terrain roughness (e.g., whether the flow is over water, forests, suburbs, or over built-up city environments, etc.). The different flow speeds in the boundary layer cause flow shearing in the layer; after the fluid passes a body, it tends to rotate and at high enough speeds vortices can form, which are also known as eddies.^{1–6}

Figure 1 Growth of a typical two-dimensional boundary layer along a flat surface.

As the flow approaches a body in its path, it slows down on the upstream side, accelerates around the sides, and forms eddies in the downstream side. The collection of eddies is known as the *wake*. After traveling some distance downstream, the wake slowly disappears after the eddies disintegrate.¹⁻⁶ See Fig. 2.

When a fluid flow meets a structure, the flow is affected by its geometrical shape. Bodies that do not have a streamlined shape (i.e., bluff bodies) have a different effect on the fluid flow than those that do (i.e., streamlined bodies). Cables, wires, and cylindrical exhaust stacks and chimneys can be considered to be bluff bodies.¹⁻⁹ Some asymmetrical bodies such as aircraft wings, turbine blades, and some automobiles are essentially streamlined when the flow approaches in the design direction. But, if the flow approaches such bodies at an abrupt angle different from the design direction, they must be regarded as bluff bodies as well.

The feature that distinguishes the flow around bluff bodies from that around streamlined ones is that a significant wake is formed behind bluff bodies. (See Fig. 3.) The wake is separated from the rest of the

Figure 2 Organized eddies in a flow that dissipate into a disorganized wake.

Figure 3 Plan view of flow past a body, showing stagnation point (I) separation, and eddy formation: (a) square cylinder¹ and (b) circular cylinder. (From Ref. 1.)

flow by a shear layer. In the case of bluff bodies with sharp corners the shear layer begins at the corners as shown in Fig. 3a, and the flow separates from the body contour at these locations. With bluff bodies such as circular cylinders (Fig. 3b), flow separation is delayed. In the latter case a shear layer is formed first, which is known as the *boundary layer*, and then flow reversal in the boundary layer causes flow separation at locations such as A and B as shown in Fig. 3b, past which the boundary layer becomes a free shear layer.

The exact location of these flow separation points depends on several factors including: (a) the intensity of the turbulence in the approaching flow, (b) the body shape and dimensions, (c) the surface roughness of the body, and (d) the Reynolds number.¹⁻¹⁰

The static pressure (also known as the gauge pressure) in the flow depends upon the flow speed. Along any streamline, the pressure and flow velocity are related by the Bernoulli equation:

$$p_1 + \frac{1}{2}\rho U_1^2 = p_2 + \frac{1}{2}\rho U_2^2 = \text{constant} \quad (1)$$

where p_1 and p_2 are the static pressures at two points in the flow on a streamline, ρ is the fluid density, and U_1 and U_2 are the corresponding flow velocities at the two points 1 and 2. The quantity $\frac{1}{2}\rho U^2$ is called the dynamic pressure denoted by q . At some upstream locations on the body the flow slows down, some of the dynamic head is lost, and the static pressure is increased according to Eq. (1). On the body's sides the flow velocity increases again, and the static pressure drops.

If the flow comes to a complete stop at any location, the point is known as a *stagnation point* (see, e.g., point 1 shown in Figs. 3a and 3b). The pressure is the sum of the static pressure and the dynamic pressure $\frac{1}{2}\rho U^2$. Further downstream from these locations the fluid stream can separate from the body forming regions of separated flow. The different static pressures around the body give rise to the well-known lift and drag forces, which are perpendicular to and in the same direction as the flow, respectively^{1,3} (see Fig. 4). In Fig. 4 the flow approaches the body at an angle α to the x axis. The angle α is known

Figure 4 Lift and drag forces on a body.

as the angle of incidence. In aeronautics, it is often called the angle of attack.

The viscous and inertia forces and their relationship to each other affect the characteristics of the flow around the body.^{1,7} The ratio of the inertia and viscous forces can be shown to be the Reynolds number, Re , which is given by

$$Re = \rho UL/\mu = UL/\nu, \quad (2)$$

where L is a typical body surface dimension, μ is the fluid *dynamic viscosity*, and $\nu = \mu/\rho$ is called the fluid *kinematic viscosity*.

2.2. Vortex Formation

Long cylindrical structures such as machinery heat exchanger tubes, which the flow strikes perpendicularly, shed vortices (eddies) in the wake. The vortices are shed periodically and give rise to periodic lateral (lift) forces on the cylinders. This phenomenon is observed in the case of wind flow on slender circular cylindrical structures such as cables, chimney stacks, towers, masts, etc.¹⁻⁹ (see Fig. 5).

It also exists to a somewhat lesser degree on similar noncircular structures. (See Fig. 6.) Further discussion on eddy formation on circular cylinders follows.

Figure 5 (a) Flow visualization of close wake behind a circular cylinder and (b) vortex street downstream of a circular cylinder. Copyright Onera (www.onera.fr), the French Aerospace Lab.

Figure 6 Wake downstream of a thin plate immersed in a water flow. Copyright Onera (www.onera.fr), the French Aerospace Lab.

The Strouhal number S is defined as

$$S = nd/U \quad (3)$$

where n is the vortex shedding frequency (in Hz), d is the characteristic structural dimension (in m), and U is the flow velocity (in m/s). For a long slender cylinder, the characteristic dimension d is typically chosen to be its diameter.

Figure 7 shows, for smooth circular cylinders, the flow dependence on Reynolds number.¹⁻⁹

In the case of noncircular slender prismatic structures, the Strouhal number is similarly defined; the characteristic dimension d is normally chosen to be the

Figure 7 (a) Flow past circular cylinder $Re \approx 1$, (b) flow past circular cylinder $Re \approx 20$, (c) flow past circular cylinder $30 \leq Re \leq 5000$, (d) flow past circular cylinder $5000 \leq Re \leq 200,000$, and (e) flow past circular cylinder $Re \geq 200,000$. (From Ref. 1).

across-wind dimension. Table 1 gives Strouhal numbers for a selection of closed shapes (Table 1a) and for open and cylindrical shapes (Table 1b). It is seen that the Strouhal number for closed shapes depends not only on the across-flow dimension d but on the along-flow dimension B and the leading-edge radius r as well. The range of Reynolds number in which the Strouhal number is valid is also given in Table 1a.⁶

Using the characteristic dimension of the body and the flow velocity, the Strouhal number S can be used to predict the frequency of vortex shedding in the structure's wake. For cylindrical structures, the Strouhal number may be assumed to be about 0.2 and to be nearly independent of Reynolds number. The numbers given in Table 1 should be used for guidance only. Figure 8 shows some experimental results⁶ for

2.3 Added Fluid Mass

Structures immersed in moving fluids are exposed to a variety of dynamic forces that can cause vibration of the structures. However, it is well known that the fluid itself has an effect on the dynamics of structures. This effect is most pronounced in cases where the fluid density is comparable with the density of a structure. As a structure moves, it entrains some of the fluid, effectively increasing the structure's mass. The effect is independent of the fluid viscosity. The mass of the entrained fluid is normally termed the *added mass*. This added mass has the effect of reducing

the natural frequencies of the structure. It also has the effect of coupling together the modes of vibration of the structure and the vibration of structural elements situated near to each other in the fluid.⁷

The response of a structure to a dynamic force is related to its stiffness, damping, and effective mass. Extended structures have a low fundamental natural frequency and multiple higher natural frequencies. In many cases vibration in the fundamental frequency is dominant.^{3,6,51} At a frequency below a natural frequency, the structural response is stiffness controlled. At or near to a natural frequency the response is damping controlled, and above a natural frequency it is mass (or inertia) controlled. Thus the added mass is seen to have most effect on the high-frequency vibration of light structures immersed in dense fluids. Proper modeling of the vibration of ship hulls in water, structural elements of pumps conveying dense liquids, and the dynamics of ship propellers, liquid heat exchanger tubes, and the like must always account for fluid mass loading and inertia effects.⁷ It can be shown theoretically that the added mass is proportional to the mass of fluid displaced by the structural element.⁷

If two structures are situated close to each other, the added mass also becomes a function of the spacing between the structures and in addition inertial coupling will exist between them. Several books present tables of added mass for various structural geometries.^{3,7} If the structure is axisymmetric, the added mass is easily calculated and the motion effects are symmetric about the length axis. If a structure is asymmetric, it can be shown that the added mass couples motion in the X - and Y -orthogonal directions and has an

Figure 9 Flow in multitube heat exchangers of nuclear or thermal power stations. Copyright Onera (www.onera.fr), the French Aerospace Lab.

effect on torsional motion as well.⁷ Figure 9 shows an experimental visualization of the flow in multitube assemblies such as those found in a heat exchanger in a nuclear or thermal power station. The interaction of the vortices in the wakes of upstream cylindrical structures with those downstream can be seen clearly. It can also be observed that the interaction between upstream and downstream cylinders varies with time as eddies are shed alternately from the top (right) and bottom (left) of the upstream cylinders.

For the theoretical case of a simple mass–spring–damper system, much above its natural frequency, the acceleration response of the structure to a given force is proportional to its mass. For real extended structures with multiple natural frequencies, the situation is more complicated, but at high frequency and for excitation that is not near to any natural frequency, the structure's mass is normally the dominant effect that governs its response. Thus the added mass effect is more important for light structures and at high frequency.

In cases where water or some dense liquid is the fluid medium, then mass loading effects are important and must be considered. However, for air or some other fluid medium such as natural gas, added mass effects can normally be ignored in practice. Since the rest of this chapter will be concerned mainly with the response of structures to wind forces, added mass will not be considered further.

3 WIND CHARACTERISTICS

The wind flow speed and direction normally continually change. The wind in most cases is highly turbulent, and its characteristics depend on a number of factors, the most important being: (a) the surface roughness of the terrain (which differs according to whether the surface is water, open terrain, suburban, or urban) and (b) the height above the ground.^{1–5}

3.1 Variation of Wind Velocity due to Height above Ground Level

Figure 10 represents the instantaneous velocity profile of wind with height above the ground, z . The wind

Figure 10 Instantaneous wind profile $U(z,t)$ with superimposed turbulence as a function of height, z .

flow velocity varies with height because of the addition of the turbulent flow to the mean flow. A time average of the flow is shown as the mean flow profile given in Fig. 10. The averaging time used must be significantly greater than the time of passage of the wind flow over the body d/U , where d is a characteristic dimension in the flow direction and U is the flow velocity.

3.2 Effect of Terrain

Buildings and other obstacles have the effect of slowing down the wind. This causes a large difference between low- and high-elevation wind velocities. In open country there is less difference between low- and high-level wind velocities. Figure 11 shows typical wind speed profiles in open country (rural), suburban, and city terrains. Both average (mean) speed profiles and an indication of the range of gust fluctuations are given. The gradient wind speed is the undisturbed wind speed expected at high elevation. The profiles can be predicted if the surface roughness factors expected for each terrain are known.^{1–5}

Figure 12 presents typical wind boundary layer velocity profiles for three different areas. The height, z , above the ground is given in the vertical scale in metres. Wind velocities are expressed on the horizontal scale as a percentage of the *gradient* (or upper level undisturbed) wind velocity.

3.3 Wind Flow around Buildings

Wind speeds and profiles are typically referenced with respect to a standard height of 10 m (33 ft) above ground level. See Fig 13. It can maintain a fairly

Figure 11 Vertical profiles of mean wind velocity for three typical terrains.

Figure 12 Typical wind velocity profiles: town or city (*left*), suburban (*center*), and rural or open country (*right*) landscapes.

steady direction, but it can also change in speed and in direction (known as veering). When an obstruction such as a building is encountered, the flow pattern changes markedly. (See, e.g., Fig. 14.)

Buildings introduce distinct individual wind flow patterns. Near large buildings the wind can behave in a very complicated manner due to local flow accelerations, formation of eddies, and flow reversals. For example, winds can reverse direction and head downward in the “upwind roller” that can form in front

of a large tall building. The wind can also roll and flow upward behind such a building. (See Fig. 15.)

By watching the behavior of vegetation, birds in flight, flags flying, and the like near a building, it is possible to observe such wind flow patterns in real life. The use of scale-model buildings in wind tunnels makes it possible to reveal such wind flows by the use of flow visualization techniques (e.g., smoke). Wool or cotton tufts attached to the model building and ground surfaces are also used sometimes for flow visualization.

Figure 13 Typical wind velocity profiles in city and open country regions with velocities of 8 km/h and 16 km/h referred to a height of 10 m.

Wind velocities vary widely in different parts of the world. For example, in England and Wales, large cities and towns rarely experience wind gusts that exceed 110 km/h (stagnation pressure $p = 560$ Pa) (70 mph). Coastal areas can have gusts of up to 145 km/h (stagnation pressure $p = 970$ Pa) (90 mph). Some areas in the north of England and Scotland can be subjected to gusts that exceed 160 km/h ($p = 1185$ Pa) (100 mph.)

3.4 Wind Stagnation Pressure and Flow around Buildings

The stagnation pressure can be calculated from Eq. (4), which is based on the Bernoulli equation, Eq. (1)

$$p = 0.6U^2 \quad (4)$$

(a)

(b)

Figure 14 Wind flow around a building. (a) section view and (b) plan view. (+) = Positive gauge pressure; (-) = negative gauge pressure. Flow normally separates at the sharp upstream corners of the building. Reattachment in some cases occurs before the wake is formed. (1 = stagnation point, 2 = separation points, and 3 = reattachment points).

Figure 15 Schematic diagram of airflow patterns around a bluff-body or building.

The constant 0.6 is approximately half the specific mass of air, at 20°C and average relative humidity. For example, a strong gale-force wind blowing with a free stream velocity of 80 km/h (48 mph) could exert a maximum stagnation pressure of 296 Pa on a building:

As the air passes over and around the building, the static pressures are positive (relative to gauge pressure) on the upstream windward side and negative (relative to gauge pressure) on the downstream (leeward) or sheltered side. The negative pressures can cause the roofs to be “sucked off” buildings and windows out of walls. If the wind comes to a complete stop at a stagnation point, its dynamic pressure far upstream is fully converted into a static pressure.

The maximum wind force exerted on a building can be considerable. The wind force normally varies over a

building surface, and the total wind force usually does not exceed 80% of the maximum theoretically possible value.

Example Consider a building with 15-m wide \times 6-m high wall exposed to 160 km/h gusts in an exposed coastal area in Scotland:

$$\text{Wind pressure} = 1185 \text{ Pa}$$

Actual force transmitted to building will be between 50 and 80% of theoretical maximum, depending on surface roughness of the building.

$$\begin{aligned} \text{Estimated maximum total force on building} \\ = 15 \times 6 \times 1185 \times 80\% \text{ N} = 87.7 \text{ tonnes} \end{aligned}$$

The Beaufort scale is used in some countries as a measure of wind strength. Table 2 shows Beaufort scale number ratings for several different wind descriptions and speeds, together with corresponding stagnation pressures.

3.5 Duration of Average Wind Speeds

Wind conditions vary from day to day and month to month in most parts of the world. Table 3 gives average wind speeds and the fraction of the time winds are above 8 and 16 km/h in the United Kingdom.

3.6 Wind Excitation of Buildings

The wind excitation forces on building structures may be divided into two main categories: (a) fluctuating forces in the wind direction on the structures caused by the turbulent pressure fluctuations that exist in the approaching wind flow and (b) fluctuating forces caused by turbulent eddies shed in the wake of the structure. These eddies (vortices) shed in the structure's wake mostly result in fluctuating forces

in the cross-wind direction and to a lesser extent in the torsional direction. Wind excitation forces and the building vibrations they cause may be further subdivided and are now described in more detail in the following sections in this chapter.¹⁻⁹

As discussed already, the response of a building structure to wind depends not only on the wind characteristics but on the structure parameters as well. Very stiff structures deflect little in the wind, and their response can be treated as simple random forced response problems. However, flexible structures such as road signs, tall bridges, tall buildings, communication towers, and the like can respond appreciably and their movement can change the flow. The interaction of the structure motion and flow is known as an aeroelastic phenomenon. The calculation of the aeroelastic response of building structures is much more complicated than that of a pure forced response problem. Although many attempts have been made to calculate the response of rigid and flexible building structures to wind, many unknowns and variables in the wind flow, speed and direction with time, height above the ground, interactions with other structures, and complicated building geometries make calculations difficult.^{1-6,8,9} In most cases, scale models need to be tested in wind tunnels to obtain reliable results.

Figure 16 shows a schematic of wind effects and building excitation effects.

3.6.1 Turbulence-Induced Vibration (Gust or Buffeting) Vibration of a structure may be caused by turbulence in the oncoming flow. The unsteady velocities and related pressure fluctuations in the approaching flow produce unsteady loading on the structure. The response of the structure caused by this unsteady loading is often termed *buffeting*. If the turbulence in the oncoming flow is associated mostly with turbulence in the wake of an upstream structure, the loading and structural response is usually called *wake buffeting*, although some refer to the phenomenon as *turbulence-induced vibration* or *gust-induced vibration*. The turbulent gusts cause fluctuating drag and lift forces on the structure and resulting inline, across-wind, torsional vibrations, and a combination of all three effects.^{1-6,8,9}

3.6.2 Wake-Induced Vibration (Buffeting) If a structure is downstream of another structure, it will be subjected to the turbulent wake shed from the upstream structure. If the separation between the structures is only a few typical building dimensions, then the downstream building can be subjected to periodic excitation caused by the vortices shed alternately from the left and right sides of the upstream structure. (See Figs. 5, 6, and 9.) If the direction of the wind is such that only the vortices from one side of the upstream structure strike the downstream structure, the excitation frequency will be only half as much as in the case where vortices from both sides strike the downstream structure. If the wind is very turbulent and it veers in direction, then the vortices will strike the downstream structure aperiodically. Some of the time vortices may strike the downstream structure, and the

Table 2 Beaufort Scale Ratings and Stagnation Pressures for Different Wind Conditions and Speeds

Wind Speed			Wind Description	Beaufort Scale	Stagnation Pressure (Pa)

rest of the time they may miss the structure completely, which may be in free flow conditions the rest of the time. At a considerable distance downstream, the wake will have become disorganized (see Fig. 2), and the excitation forces will become more random in nature. The wake effect depends also on the flow velocity, and, as Fig. 7 shows, it can be related more accurately to the Reynolds number. Methods for the calculation of the response of structure to inline buffeting are given in several recent publications.^{1-6,8,9,15} The methods are too complicated to give in detail here.

3.6.3. Vortex-Induced Vibration In the case of slender cylindrical structures such as chimneys, towers, and masts, vortices are shed alternately from the left and right of the structure in the wind direction in the wake. (See Figs. 5, 6, and 7.) This phenomenon gives rise to oscillating forces in the cross-wind (or lift) direction at the vortex shedding frequency, n . If the structure is very stiff, and the motion is negligibly small, then it can be regarded as forced motion. If the structure is extended as in the case of a tall flexible building, and the natural frequencies of the building are close to the Strouhal frequency, the structural motion can affect and significantly interact with the flow so that the motion of the body causes the eddies to be shed at the same frequency as the body vibration and this is no longer strictly related linearly to the wind speed. This important effect is known as *lock-in* and is observed experimentally to result in a considerable amplification of the structural motion. The motion can result in large vibration amplitudes, but not usually greater than half of the cross-wind dimension of the structure.^{1-6,8,9,15} Theoretical analyses are not yet completely successful in predicting the full range of lock-in vibrations of flexible structures.^{2,6,15} The motion is illustrated in Fig. 17.

Galloping is an aeroelastic phenomenon. It is more prevalent on slender structures such as ice-coated

power lines and slender flexible masts with rectangular cross sections and other open sections such as H, I, U, and so forth. See Table 1b. Galloping can occur in a variety of manners. One common form of galloping is *across-wind galloping*. Large motions of the structure can result in across-wind vibration with amplitudes up to 10 times or even more of the across-wind dimension of the structure. The motion can be explained physically as follows. As the structure moves, its velocity relative to the oncoming wind velocity increases the angle of incidence (sometimes also called angle of attack) α of the wind to the structure. This increase in angle increases the lift forces on the structure. These increased forces cause further across-wind deflection and so on. The oscillatory motion is only limited when the structural velocity relative to the wind velocity no longer produces an increase in across-wind force with increase in the relative angle of attack. Some authors treat this motion as a nonlinear phenomenon and theories have been formulated to predict the effect and motion. Often the static lift and drag coefficients are used for first approximations of the lift and drag forces needed in a theoretical analysis.^{2,6}

Across-wind galloping can occur at any wind speed. Surprisingly, galloping is often observed at low to moderate wind speeds. This is because with a low wind velocity, the structural velocity is appreciable compared to the wind velocity and causes a considerable change in the relative angle of attack α of the structure to the wind. See Fig. 4.^{1-6,8,9,15}

Torsional galloping is similar to across-wind galloping. With torsional galloping, torsional (twisting) vibration is involved in place of across-wind vibration. Such across-wind and torsional galloping motions are inherently unstable and can result in violent motions and even eventual structural failure.²

Figure 17 Vortex resonance: (a) synchronization of vortex shedding and structure frequencies and (b) across-wind vibration amplitude (y/d) referred to reduced wind speed $U_r = u/df_e$. (From H. Bachmann et al., Ref. 6. Reprinted with permission).

3.6.4 Flutter Flutter is similar to galloping, but here across-wind and torsional vibrations may be excited simultaneously. Like galloping, it is an aerodynamic instability. Unlike galloping, however, which is largely a single-degree-of-freedom phenomenon, flutter is a two-degree-of-freedom phenomenon. Vortex shedding is not involved. The torsional and the across-wind motions are coupled together.^{1,2}

Several types of flutter have been observed.² *Classical flutter* is well known to aircraft designers, particularly with the wings themselves and the control elements on the wings (ailerons). If the structure has natural frequencies of vibration in the across-wind (lateral) and torsional modes, which are very close to each other, then with small changes in structural position or geometry, the two frequencies of vibration can be caused to coincide and flutter commences.

Stall flutter normally occurs when the wind is at an oblique incidence to the structure and when structural or airfoil stall is involved.^{1,2} As the relative angle of attack increases, if the relative angle of attack is sufficient to reach and increase past the angle of stall, the lift force can be suddenly lost. Such flutter can result in very large vibration. Road signs mounted on a central cylindrical post are prone to such vibration. The vibration can be suppressed by increasing the stiffness of the supporting post and/or the structural damping.

Panel flutter is observed on aircraft and spacecraft fuselage and wing panel structures but can be observed on flexible building or bridge facings too, for instance, on sheet metal roofs. In such cases the motion is again self-excited, affects the fluid flow, and is unstable. It can be suppressed by geometrical redesign and/or increase in panel vibration damping.^{1-6,8,14,51}

4 STRUCTURAL VIBRATION RESPONSE OF BUILDINGS AND TOWERS

Figure 18 presents a schematic that indicates the vibration amplitude responses of a building structure to the different types of excitation discussed in Sections 3.6.1 to 3.6.4 and as classified in Fig. 16.

4.1 Types of Building Vibrations

As already discussed in Section 3 of this chapter, fluid flow and wind forces are responsible for a variety of vibratory mechanisms in structures. In the case of inline buffeting, (Fig 18a), the vibration amplitudes generated increase nonlinearly and very rapidly with flow speed. This is because motion can be regarded as forced motion, and the turbulent flow forces involved are proportional to flow velocity squared. It is important to know the fundamental natural frequency of a structure if it is in forced motion since below the natural frequency the response is mostly stiffness controlled, at or near to the natural frequency is damping controlled, and above the natural frequency it is mass (or inertia) controlled.

In cross-wind vortex shedding motion (see Fig. 18b), again a knowledge of the structural fundamental natural frequency is needed since by careful building design, it may be possible to modify this frequency and change it so that it only becomes a problem at low wind speed at which excitation forces are minimal.

In cases of aerodynamic instability (galloping or flutter) such instabilities only begin at a critical wind speed, and again the natural frequencies of the structure are involved in the vibration as described before in Section 3.6 of this chapter.

4.2 Natural Frequencies of Building Structures

The natural frequencies of a building can be calculated from knowledge of its stiffness and mass distributions

Figure 18 Main types of wind-induced oscillations: (a) vibration due to turbulence, (b) vibration due to vortex shedding, and (c) self-excited vibration due to aerodynamic instability.

with a numerical program such as the finite element method (FEM). Figure 19 shows a schematic distribution of the mass and stiffness distributions of a 210-m telecommunications tower.⁶

The first three natural frequencies and mode shapes of vibration of the tower are shown in Fig. 19. These are seen to be very low, the first two being less

than 1 Hz. Often vibration in the fundamental natural frequency is dominant and most important.

Although FEM programs can be used to calculate the fundamental natural frequency, it has been found that the calculation is no more accurate than using an empirical calculation based on the height of the building alone and use of an approximate formula such

Figure 19 Telecommunications tower with mass distribution, stiffness distribution, and natural modes of vibration. (From H. Bachmann et al., Ref. 6, Reprinted with permission).

as Eq. (5).^{6,31}

$$f = 46/h \quad (5)$$

where h is the building height in metres.

The reason that the fundamental natural frequency is dominated by the building height appears to be that as the buildings grow taller they become more massive, and then stiffer supports must correspondingly be used to support the building's weight. Figure 20 shows measured experimental data for building height plotted against fundamental natural frequencies of a large number of tall buildings. Equation (5) is also plotted in Fig. 20. It is seen that this equation is a good fit to most of the experimental data.

Figure 21 shows that buildings of height even greater than those plotted in Fig. 20 have been constructed. The fundamental natural frequency of a building is of considerable importance, but so are several other building properties. Since there is a continuing trend to construct building structures of increasing height, wind-induced vibration of tall structures is a topic of increasing concern for structural engineers. The three most important properties of structures that are relevant to wind-induced vibration are: (1) shape, (2) stiffness (or flexibility), (3) fundamental natural frequency, and (4) damping. (See Fig. 22.)

5 METHODS OF BUILDING STRUCTURE VIBRATION REDUCTION AND CONTROL

When structures are excited into motion, the forces opposing the motion are due to inertia, stiffness, and damping.

Figure 20 Fundamental frequency f_e of tall buildings. (From H. Bachmann et al., Ref. 6. Reprinted with permission.)

It is impractical to increase the mass of the building. Increasing the stiffness of a building can, in principle, reduce its deflection to wind forces, although often

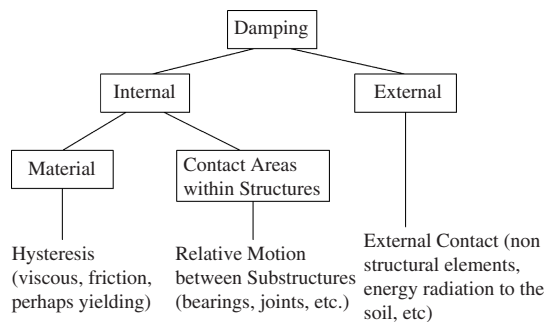

Figure 23 Various types of damping.

there is a limit to the amount of stiffness increase that can be achieved. However, useful increases in stiffness can be achieved relatively easily in the case of masts, antennas in some cases by the use of guy wires and cables. The dynamics of guyed masts are complicated because tensioning of the guy cables is applied and the vibrations of the guy–mast system tend to be nonlinear in character. The guy cables themselves normally vibrate, resulting in some useful damping.⁶ Various types of structural damping are illustrated in Fig. 23.

For wake buffeting, across-wind vortex-induced vibration, galloping, and flutter, damping forces become dominant in controlling vibration. Passive damping can be applied successfully in such cases. Different passive damping elements have been used in practice, and several new designs have been proposed. The World Trade Center in New York had about 10,000 passive “friction” dampers mounted in the truss structures. (See Fig. 24.)

Tuned vibration dampers (TMD) are also now used in many tall buildings. The first tall building to have such a device was the 280-m high Citicorp Center in New York City (Fig. 25). This employed a 270,000-kg concrete block “floated” on a hydrostatic support system. Springs are attached to the mass and tunes to

Figure 24 Friction dampers used in the load-bearing structure of the now-destroyed World Trade Center towers (New York City).

give the TMD system a natural frequency the same as the fundamental vibration frequency of the building. In addition, hydraulic dampers are applied to dissipate the vibration energy. Stops must be provided to prevent excessive damaging motion of the floating mass during intense storms. A problem is that electrical power is needed to provide hydrostatic pressure for the oil suspension system. If the electrical power fails during a storm, then the TMD system becomes inoperative.

The principle of operation of the tuned mass damper is that as the building vibrates at its natural frequency, the tuned damper will also vibrate at the same frequency, but out of phase and thus applying forces opposing the motion of the building.

More recently, tall buildings have used TMDs made of large masses suspended by cables, rather like pendulums. The 500-m building in Taiwan opened in November 2004 has a 500,000-kg mass suspended on four cables near the top of the building between the 86th and 89th floors. See Figs. 26 and 27. As the building vibrates, the mass swings in an opposite direction, and pneumatic dampers are used to dissipate vibration energy. Excessive damaging vibration is prevented by the dampers. The system is mainly designed to reduce wind-induced vibrations by 35%, but it is said to also suppress earthquake vibrations. Since the building is situated only 1 km from a

Figure 25 Vibration absorber, Citicorp Center, New York. (From H. Bachmann et al., Ref. 6. Reprinted with permission).

Figure 26 (a) Photograph and (b) construction drawing of Taipei 101 skyscraper in Taiwan.

Figure 27 Photographs of tuned mass damper (TMD) ball in Skyscraper Taipei 101 in Taiwan.

fault line, earthquake damage is of concern. During construction in 2003, a 6.8-scale earthquake was experienced. The building survived the earthquake and the tuned mass system is said to have worked satisfactorily, although a construction crane fell from the 50th floor during the earthquake killing five construction workers.

Other types of damping systems have been proposed and in some cases implemented. Some such dampers rely on liquid motion inside rigid containers to absorb and dissipate the vibration energy. For example, nutation dampers have been investigated by Modi and Welf.⁵² Tuned liquid dampers (TLD) and tuned liquid column dampers (TLCD) have been investigated for use in buildings by Sakai et al.⁵³ and Xu et al.³⁸ These dampers have been used successfully in spacecraft satellites and marine vessels by Amieux and Dureigne.⁵⁴ TLD and TLCD systems have some advantages over TMDs, including lower costs, less maintenance, and easier construction and handling.³⁸

As discussed before, circular section structures, like chimneys, mast, and cooling towers are prone to across-wind vortex excitation. The vortex shedding can be reduced and suppressed to some degree by the use of strakes, shrouds, slats, and the like as shown in Fig. 28. The strakes, shrouds, and slats can reduce the coherence of the vortex shedding along the

Figure 28 Methods of reducing vortex-induced vibration in cylindrical structures.

Figure 29 Human perception of building vibration due to wind. (See Ref. 50.)

cylindrical structure, but their effectiveness depends to some extent on the Reynolds number of the flow.^{1,4,6}

6 HUMAN RESPONSE TO VIBRATION AND ACCEPTABILITY CRITERIA

In most cases, building vibration caused by wind is insufficient to cause structural damage, except in some cases to the superstructure or cladding. (See Fig. 29.) The vibration is, however, often unpleasant and worrying for occupants. The swaying of tall buildings particularly at the tops can be disconcerting for occupants to say the least. Most studies on acceptability of vibration have been for frequencies higher than those normally encountered in tall buildings. Some studies have been conducted with very low frequency vibration using vibration simulators. Other results have been obtained from extrapolations from high frequency to low frequency to arrive at criteria for acceptability of vibration at very low frequencies less than 1 Hz. Most subjects report that they cannot sense vibration with acceleration less than about 0.01 g . If the vibration has an acceleration exceeding about 0.1 g , most subjects find the vibration

Table 4 Human Acceleration Acceptability Criteria

Perception	Acceleration Limits
Imperceptible	$a < 0.005g$
Perceptible	$0.005g < a < 0.015g$
Annoying	$0.015g < a < 0.05g$
Very annoying	$0.05g < a < 0.15g$
Intolerable	$a > 0.15g$

Source: From Refs. 1, 6, and 50.

is becoming intolerable. Table 4 lists some human acceptability criteria.

7 USE OF WIND TUNNELS AND SCALE MODELS

In some cases, it is difficult to predict the wind flow around and forces on buildings from previous knowledge, published studies, and existing empirical prediction schemes and theoretical models. Such cases include building designs with complicated or unusual shapes, buildings in the downstream wake of other buildings or groups of buildings. In such cases, the testing of scale models in wind tunnels should be considered.

Since wind tunnel testing can be expensive (on the order of \$20,000 to \$100,000 in 2005), it is normally only considered for the design of larger buildings and structures where the cost savings is greater than the wind tunnel tests. Wind tunnel testing of model buildings and structures and model scaling and similarity laws for the flow are described in several publications.^{1,2,4,5,18}

CHAPTER 117

PROTECTION OF BUILDINGS FROM EARTHQUAKE-INDUCED VIBRATION

Andreas J. Kappos and Anastasios G. Sextos

Department of Civil Engineering
Aristotle University of Thessaloniki
Thessaloniki, Greece

1 INTRODUCTION

Earthquakes are generated wherever the accumulation of strain at geological *faults* leads to their rupture and slip, until a new stable state is reached. There are essentially two types of faults, those associated with horizontal (*strike-slip*) and those associated with vertical (*dip-slip*) movement. The waves generated propagate either by compression and dilation with the ground particle motion in the same direction as the propagation (*longitudinal* or *P waves*) or by shear (*transverse* or *S waves*); both types are referred to as *body waves*. When body waves reach the Earth's surface, they are reflected back into the crust, and a vibration of the surface is initiated, which propagates through *surface waves*. Surface waves, along with S waves, account for the strongest part of seismic motion, that is, these are the potentially more destructive. Protection of buildings from earthquake-induced vibration, therefore, is the process to estimate the amount of energy (often related to *magnitude*) that is expected with a specific probability to be released at the *source*, to establish methods for determining the *frequency content*, *duration*, and *intensity* of ground motion that finally excites the structure, and to define methods for calculating and optimizing the structural dynamic response to this vibration.

2 CONCEPT OF SEISMIC DESIGN OF STRUCTURES

Protection of buildings from earthquake-induced vibration is achieved through their *seismic design*. The goal of seismic design is to ensure that a structure behaves "satisfactorily" when subjected to earthquake loading. As is the case with most loading types, the anticipated behavior or performance levels for the structure are different for different levels of the loading. Ideally, and taking into account the large uncertainty associated with earthquake loading, several levels of performance should be considered in design, each one corresponding to a different probability of exceedance of the seismic loading. According to most current seismic codes, the structure should resist minor earthquakes (i.e., remain serviceable at its serviceability limit state) without significant damage, sustain moderate earthquakes (i.e., at its ultimate limit state) with repairable damage, while avoiding collapse during major earthquakes. This points to the need to design a structure for a set of performance objectives (limit states), recently referred to as performance-based design (PBD).¹ Through the

code-defined design procedure, therefore, the engineer is provided with the seismic loads that the structure should be able to withstand in order to meet the above objectives, the minimum design requirements and the detailing rules that ensure the desired performance as well as with the methods of structural analysis to be employed in order to determine the response of the structure under the design loads.

For a given level of seismic exposure, it can be generally claimed that structures built in industrialized countries aware of the seismic risk are in general adequately safe (less vulnerable), but the expected actual cost of damage inflicted, as well as the indirect cost resulting from business disruption, need for relocation, and the like can be significantly higher. As a result, the *seismic risk* of potential economic losses is in fact a qualitative product of *seismic hazard* (i.e., the level of seismic exposure), *structural vulnerability* (i.e., the level of expected damage), and *element value at risk* (defined by the importance of the structure). It has to be noted though that seismic risk modeling is a useful decision-making and risk management diagnostic tool that does not provide solutions alone; it is the code-prescribed design and assessment process that guarantees compliance with the structural performance criteria.

3 FUNDAMENTALS OF BUILDING RESPONSE TO EARTHQUAKE

3.1 Single and Multiple-Degree-of-Freedom Systems

The simplest model of a structure that can be considered is a single-degree-of-freedom (SDOF) pendulum having its mass concentrated on top and vibrating laterally under base excitation, while its resistance is exclusively provided by the total stiffness k of its vertical elements (a one-story building or an elevated water tank are some typical examples). When a force that varies with time $p(t)$ is applied on this structure with mass m , the resulting displacement, denoted by $u(t)$, is a function of the system damping force f_D and the stiffness-related resisting force f_s . Newton's second law of motion leads to the fundamental equation:

$$m\ddot{u} + c\dot{u} + ku = p(t) \quad (1)$$

which for the particular case of base excitation (due to earthquake) is written in the form:

$$m\ddot{u} + c\dot{u} + ku = -m\ddot{u}_g(t) \quad (2)$$

The solution of the above equation is obtained by adding the response of the SDOF system to the so-called effective earthquake force $p_{\text{eff}}(t) = -m\ddot{u}_g(t)$ for all impulses up to the particular time t :

$$u(t) = \frac{1}{m\omega_n} \int_0^t p_{\text{eff}}(\tau) \sin[\omega_n(t - \tau)] d\tau \quad (3)$$

where $\omega_n = \sqrt{k/m}$. Equation (3) is known as *Duhamel's integral*, and it is a special form of the convolution integral.

For the case of multiple-degree of freedom systems (corresponding to the vast majority of engineering structures), nodal displacement is a vector that can be expressed in terms of particle modal contributions as

$$u(t) = \sum_{r=1}^N \phi_r q_r(t) = \Phi q(t) \quad (4)$$

where ϕ_r are the modes of the system and $q_r(t)$ the modal coordinates. Using this transformation, eq. (1) can be written in the form:

$$\sum_{r=1}^N m\phi_r \ddot{q}_r(t) + \sum_{r=1}^N c\phi_r \dot{q}_r(t) + \sum_{r=1}^N k\phi_r q_r(t) = p(t) \quad (5)$$

By multiplying each part of the equation by ϕ_n^T and by substituting the *generalized mass*, *stiffness*, and *force* components being, respectively, $M_n = \phi_n^T m \phi_n$, $K_n = \phi_n^T k \phi_n$, and $P_n = \phi_n^T p \phi_n$, the N equations expressed in Eq. (5) are summarized in matrix form:

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{P}(t) \quad (6)$$

where \mathbf{M} is the diagonal matrix of the generalized modal masses M_n , \mathbf{K} is the diagonal matrix of the generalized modal stiffness K_n , and $\mathbf{P}(t)$ is a column vector of the generalized modal forces $P_n(t)$.

3.2 Elastic Spectra and Design Spectra

A *response spectrum* is a plot of the peak response (to the aforementioned effective earthquake force) as a function of the natural period and can be derived by analyzing a series of SDOF systems, as can be seen in Fig. 1. It is explained in more detail in the literature.²⁻⁴ The quantities typically plotted are the spectral pseudoacceleration S_{pa} , pseudovelocity S_{pv} , and displacement S_d , which are interrelated through the familiar expressions

$$S_{pa} = \omega S_{pv} = \omega^2 S_d \quad (7)$$

For design purposes, S_{pa} is more useful than the actual response acceleration since the former can be used to

Figure 1 Pseudoacceleration and absolute acceleration response spectrum plots.

Figure 2 5% damped pseudoacceleration spectra for three different ground motions.

calculate directly the maximum forces on the structure. An important piece of information provided by a spectrum is the range of periods for which the response of a structure is peaking. A useful indicator of the damageability of a ground motion is S_{pv} , which is a direct measure of the seismic energy input, since for negligible damping the energy stored in an oscillator with mass m is equal to $\frac{1}{2}mS_{pv}^2$. On the other hand, recently developed *displacement-based design* and *assessment* procedures are based on the displacement spectrum. Despite those trends, current codes base their design forces on S_{pa} spectra (directly or indirectly), hence, S_{pv} and S_d curves can always be derived due to Eq. (7).

The significant differences in the shape of response spectra derived from different ground motions are illustrated in Fig. 2, which shows the 5% damped S_{pa} spectra for three accelerograms recorded in three different parts of the world. In particular, the Pacoima Dam (California) S16E and the Kalamata (Greece) N10W records are from earthquakes with similar magnitude (6.6 and 6.2) and very close to the recording station (epicentral distances of 3 and 15 km). It is seen that, although the amplitude is significantly larger for the Pacoima record, the shape of the two spectra is quite similar, with peaks occurring in the short period range. On the other hand the Mexico City 1985 transverse component, recorded at the SCT station during a magnitude 8.1 earthquake at a distance of 400 km, resulted in a significantly different spectral shape, wherein the critical period range is between 1.7 and 2.8 s. Bearing in mind that the fundamental natural period of a building frame is approximately equal to $N/10$, where N denotes the number of stories, it is seen that the Mexico City record with a peak ground acceleration (PGA) of only 0.17g, was more critical for high-rise buildings with $T > 1.7$ s than the Pacoima record with a PGA of 1.17g.

For design purposes, it is clear that spectra smoother than those of Fig. 2 are required since a future motion is very unlikely to be identical to a previously recorded one, and also the exact periods

of a structure are difficult to assess in practical situations (e.g., when stiff cladding or partition elements are present in steel or reinforced concrete (R/C) frames). A smooth *design spectrum*, therefore, encompasses a family of ground motions and is derived from a statistical evaluation of actual spectra.

The *code spectrum* prescribed by the vast majority of modern seismic codes is a function of a number of parameters that define the target level of seismic excitation that is accepted for a structure and depends on:

- The seismo-tectonic environment of each geographical region and the corresponding exposure of structures to seismic hazard
- The foundation soil conditions that characterize the site of construction
- The importance of the structure
- The amount of damping due to a number of sources (material damping, damping at connections, etc.)
- The ability of the particular structural configuration to absorb seismic energy through stable cycles of inelastic response.

Seismic codes typically specify pseudoacceleration spectra only, consisting of a shape to be anchored to a (design) PGA, which is a function of the soil category that the foundation soil can be classified into: For softer materials, the spectrum is generally shifting rightwards representing a higher level of bedrock ground motion amplification that is expected to occur when higher period pulses propagate through the (relatively) loose soil profile. Moreover, the effect of the epicentral distance on the spectral amplification at particular period ranges (as seen in the Mexico and Pacoima response spectra) has been widely recognized in recent seismic codes (e.g., the American codes since 1997) through the specification of *near-source factors*. In the latest version of the American seismic code (*IBC 2000*)⁵ the concept of spectral dependency remains intact, but the spectral acceleration is defined through the magnitude- and soil-dependent factors F_a and F_v . The latest version of the European Seismic Code, *Eurocode 8* (EN1998-1, 2003)⁶ also accounts for the effect of earthquake magnitude by distinguishing to type 1 ($M_s > 5.5$) and type 2 ($M_s < 5.5$) spectra, as seen in Fig. 3.

Based on the above, it can be stated that the spectral values are a function of both foundation soil properties, distance from the source, and intensity of the event. However, there is a number of inherent uncertainties in the definition of the appropriate soil profile determination due to the difficulty to evaluate the overall dynamic response of the soil formations from the V_s profile of the uppermost 30 m as adopted in the U.S. codes. In fact, it has been extensively shown⁷ that the dynamic material characteristics of soil profiles (described as a one-dimensional soil column) are often inadequate to depict the complex ("site effects"-related) nature and physics of the multilayered, nonlinear, three-dimensional and possibly inclined soil layers over a nonrigid bedrock.

Figure 3 Recommended type 1 elastic response spectrum for soils A to E according to *Eurocode 8* (EN1998-1, CEN 2004).⁶

A typical example of a code-specified spectrum is shown in Fig. 3, where the 5% damped elastic pseudoacceleration spectrum of *Eurocode 8* (CEN 2004)⁶ is plotted; it is calculated through the following set of expressions:

$$\begin{aligned}
 0 \leq T \leq T_B : S_C(T) &= a_g S \left[1 + \frac{T}{T_D} (\eta \cdot 2.5 - 1) \right] \\
 T_B \leq T \leq T_C : S_C(T) &= a_g S \eta \cdot 2.5 \\
 T_C \leq T \leq T_D : S_C(T) &= a_g S \eta \cdot 2.5 \left(\frac{T_C}{T} \right) \\
 T_D \leq T \leq 4s : S_C(T) &= a_g S \eta \cdot 2.5 \left(\frac{T_C T_D}{T^2} \right)
 \end{aligned} \quad (8)$$

where α = effective peak ground acceleration normalized by gravity
 T = fundamental period of the structure
 T_A, T_B, T_C, T_D = corner (characteristic) period values depending on the corresponding subsoil class as described in Table 1
 η = factor accounting for damping other than 5% = $\sqrt{5/\zeta}$ (ζ being the critical damping ratio)
 S = soil amplification parameter varying from 1.0 to 1.6

It has to be noted that the values to be ascribed to periods T_B, T_C, T_D , and S for each ground type may be found in the National Annex of each country that will adopt the *Eurocode*. Although technically feasible, designing a normal structure to respond elastically to the design earthquake forces is believed to lead to disproportionately high construction cost. For this reason, seismic design codes allow inelastic response in plastic mechanisms that are considered as favorable in terms of seismic performance and

Table 1 Soil Amplification Parameter and Corner Periods as a Function of Subsoil Class for Earthquake Type 1

Ground Type	S	T_B	T_C	T_D
A	1.0	0.15	0.40	2.00
B	1.20	0.15	0.50	2.00
C	1.15	0.20	0.60	2.00
D	1.35	0.20	0.80	2.00
E	1.40	0.15	0.50	2.00

maintain structural integrity. The relationship between elastic and design spectra, therefore, is inevitably related to the level of energy dissipation anticipated to take place through cycles of inelastic behavior and damage of the structural members.

Most of the seismic codes worldwide are influenced either by the American codes [mainly the Uniform Building Code (UBC) now replaced by the International Building Code (IBC)] or the *Eurocode*, and adopt the aforementioned concepts. An exception was Japan, which until recently was relying more on strength and much less on ductility, but this changed after the 1995 Great Hanshin (Kobe) earthquake, and stricter requirements regarding ductile detailing were introduced.

The reduction in the forces associated with the elastic spectra is usually made by dividing the elastic spectra by the “behavior factor” q (in the *Eurocodes*) or the “response modification factor” R (in the U.S. codes). It is noted that for an ordinary reinforced concrete building, the highest value according to *Eurocode 8* is less than 6, while the IBC provisions prescribe a top value of 8. It is therefore necessary, before proceeding to any comparative evaluation of code-defined spectra, to account for the different assumptions on the reduction of forces prescribed in different codes.

3.3 Design Situations

The design seismic action or the *design earthquake* is a ground motion or a set of ground motions defined in a way appropriate for the design of structures. Depending on its type and importance, the seismic action can be defined in terms of (a) a set of (equivalent) lateral forces, (b) a response spectrum, (c) a power spectrum, or (d) a set of acceleration time histories. The foregoing can be defined either on the basis of a seismic code (most common case) or by carrying out a site-specific seismic hazard analysis with due consideration of ground effects. The scope of each procedure can be appreciated by considering the following four situations that might be faced by an engineer in practical design (see Fig. 4):

- For many building structures, and also for some “small-scale” and *regular* (i.e., without abrupt changes in plan or height) civil engineering structures (such as small bridges, viaducts, etc., and typical geotechnical structures such as retaining walls), the *equivalent lateral force* procedure can be used. The procedure is well documented in most current seismic codes and will be described with specific reference to two major codes, *Eurocode 8* and *IBC 2000* code.^{5,6}
- For buildings with configuration problems (*irregular* in plan and/or elevation), for many types of “medium” bridges, and for many of the structures falling beyond the scope of this chapter, an *elastic dynamic analysis* has to be

carried out, typically in the form of modal response spectrum analysis. The definition of the elastic spectrum, the aforementioned modifications due to site effects, and its reduction to an inelastic design spectrum, are some of the most important issues relating to seismic loading.

- In cases such as the design of very important structures, or structures clearly falling outside the limits of the existing codes (e.g., structures with very high fundamental natural periods), a full *time-history analysis*, typically in the inelastic range may be required. Note that there is no advantage in using this procedure for an elastic analysis of the structure which can be conveniently carried out (at essentially the same accuracy) using the modal superposition approach, the exception being structures where due to highly irregular geometry it is difficult to combine the modal contributions, or whenever the structural model includes critical frequency-dependent parameters.⁴ An appropriate selection and scaling of natural and/or artificial records has then to be made. For *assessment* purposes, a *nonlinear static (pushover)* approach may also be performed in order to identify the expected plastic mechanism in a structure and to assess its actual capacity to resist earthquake loading.

Figure 4 Overview of the alternative analysis approaches for the seismic design of structures.

3.4 Seismic Isolation and Passive Control

Designing a structure on the basis of inelastic spectra and capacity design means that for earthquakes that exceed the design event, damage to the structure could be substantial. Perhaps more importantly, formation of a favorable mechanism does not guarantee that interstory drifts and/or floor accelerations will be low enough to prevent extensive damage to the non-structural elements. These and other concerns have led to the development of alternative conceptual frameworks for seismic design, currently referred to as active and passive control of the seismic response of the structure. The devices used in *active control* introduce an energy (or force) source into the structure. Such systems⁸ have been developed during the last two decades for reducing the response of buildings (particularly tall ones) to wind and earthquake loading. Nevertheless, despite the attractiveness of the concept and the high-quality interdisciplinary research carried out over the last two decades, the practical application of active control systems still remains very limited, mainly in full-scale demonstration projects.

As a result, by far the most practical approach, at least nowadays, is *passive control*, which incorporates the fundamental ideas of *seismic isolation* and provision of *supplemental damping*. There are two inter-related ideas behind developing a seismic isolation system: The first one is to make the structure much more flexible than it is, by altering the way it rests on the ground, hence shift it to the long period range of the response spectrum that is typically characterized by reduced accelerations (cf. Figs. 2 and 3) and consequently reduced inertial forces; the second is to introduce some kind of “fuse” between the structure and the ground, whereby the amount of base shear to be transferred from the shaking ground to the structure is controlled by the strength of the fuse. By making the structure more flexible, one might achieve lower seismic forces, but displacements tend to increase. It is therefore essential to also control the amount of horizontal displacement of the isolated structure and an efficient way to do this is by increasing its damping.

Currently, used isolation systems are based on the concept of flexible supports that can either remain essentially elastic (linear isolation) or enter the inelastic range (nonlinear isolation) upon exceeding a certain level of horizontal shear.⁹ The basic elements included in a seismic isolation system are:

- Horizontally flexible supporting devices (*isolators*) located either between the structure and its foundation or at a higher level in the structure; in buildings the flexible supports are commonly located at the superstructure–foundation interface.
- A *supplemental damping* device (or energy dissipator) for reducing the relative horizontal displacement between the superstructure and substructure (i.e., the portion of the structure below the isolators). Such devices can be of different types: *Hysteretic* dampers, wherein energy dissipation is taking place by yielding of metals;

lead–rubber bearings, which are elastomeric bearings with a lead core that provides both damping (after yield) and resistance to service lateral loads; *viscous* dampers, such as the oil dampers commonly used in the motor industry; *frictional* dampers based on friction between different materials, that is, stainless steel and PTFE (Teflon).

- Some means for controlling displacements at service levels of lateral loading, that is, wind loading and serviceability limit state (SLS) or smaller earthquake loading.

A critical point in passive control systems is that whereas isolator damping is always reducing the displacements of the structure that are controlled by the fundamental mode, it tends to increase floor accelerations caused by higher modes. This might be very important in structures where protection of secondary systems (equipment and nonstructural elements) is the main reason for using seismic isolation. Seismic attack on secondary systems is frequency selective, and it is possible to design isolation systems that reduce the response of such systems more than that of the primary structural system. A related issue is that in nonlinear isolation systems (which are used in the majority of applications), control of the amount of base shear through the strength and the stiffness of the isolators does not guarantee control of the story shear distribution along the height of the building. Whenever higher mode response is not adequately controlled, “bulged” distributions of story shear can result and in extreme cases the shear in the upper half of the structure may exceed the base shear.⁹ The foregoing are clear indications of the need for a reliable dynamic analysis when dealing with isolated structures.

A critical review of code provisions for seismic isolation can be found in Naeim and Kelly.¹⁰ U.S. code provisions (*IBC 2000*)⁵ include both the equivalent lateral force (section 1623.1.3.1) and the dynamic analysis (section 1623.1.3.4) procedures for seismically isolated buildings, but the restrictions for the former are such that in most practical cases the dynamic approach has to be applied. Two sets of verifications are required: The first one is for the design earthquake (10%/50-year probability), under which the structure is required to remain essentially elastic. The second one is a stronger event (10%/250-year probability) for which the isolation system should be designed and tested, while all building separations and utilities that cross the isolation interface should be designed to accommodate the forces and displacements associated with this seismic input. In Europe, provisions for seismic isolation of buildings have first been introduced in the final version of *Eurocode 8*.⁶

4 METHODS OF ANALYSIS UNDER EARTHQUAKE LOADING

4.1 Equivalent Lateral Force Procedures

The typical procedure in the equivalent static analysis method is the determination of an appropriate

value of the base shear in terms of the structure mass and the design earthquake intensity, properly reduced for inelastic effects, along the lines discussed in the previous section. The base shear is then used for estimating a set of lateral forces distributed along the structure following (more or less) the fundamental mode of vibration. Since the base shear itself is also calculated on the basis of the fundamental period, it is clear that the application of the equivalent lateral force method should be restricted to structures whose dynamic response is governed by the fundamental mode, that is, they are characterized by so-called *regularity* in height and plan.

The Eurocode 8 and IBC 2000 Procedures The method is referred to as *simplified modal response spectrum analysis* rather than as *equivalent static analysis*. The *base shear* (sum of horizontal loads) is calculated from

$$V_b = S_d(T_1)W \quad (9)$$

where $S_d(T_1)$ is the ordinate of the design spectrum corresponding to the fundamental period T_1 of the structure, and W is the gravity load contributing to inertial forces; this is taken as the permanent loading (G) and a portion of the variable (live) loading Q . The fundamental period T_1 can be estimated either from a proper eigenvalue analysis, or from Rayleigh's method, or from empirical formulas included in the code.

The *lateral forces* corresponding to the base shear of Eq. (9) are calculated assuming (conservatively) that the effective mass of the fundamental mode is the entire mass of the structure; hence

$$F_i = V_b \frac{s_i W_i}{\sum s_j W_j} \quad (10)$$

where F_i is the horizontal force acting on story i , s_i , s_j are the displacements of the masses m_i , m_j in the fundamental mode shape, and W_i , W_j are the weights corresponding to the previous masses.

According to the IBC 2000⁵ provisions, the method is applicable to:

- All ordinary buildings in regions of moderate to slightly more severe ground motion potential
- Irregular structures in regions of moderate to slightly more severe ground motion potential having no more than five stories
- Other structures with plan or vertical irregularities but in areas primarily located on relatively stiff soil conditions and fundamental period less than 0.7 s

The design base shear as given in the following equation is the seismic response coefficient C_s times the effective seismic weight W of the structure, that is, *seismic dead load*, including the total dead load and applicable portions of other loads (partition load of at least 0.5 kN/m², permanent equipment, etc.):

$$V_b = C_s W = \frac{S_{D1} I_E}{R T} W \leq \frac{S_{DS} I_E}{R} \quad (11)$$

where I_E is the importance factor, R the response modification factor, S_{D1} is the seismic coefficient, and S_{DS} is the minimum base shear coefficient illustrated in Fig. 5 and summarized in Table 2 as a function of the spectral response acceleration and the site class.

Two lower bounds to V_b are set in IBC 2000⁵:

- For all seismic zones

$$V_b \geq 0.44 S_{DS} I_E W \quad (12)$$

- For cases of seismic design conditions E and F where spectral acceleration $S_1 > 0.6g$:

$$V_b \geq \frac{0.5 S_1}{R/I_E} W \quad (13)$$

The fundamental period T_1 is calculated using the same procedures as in Eurocode 8⁶ [cf. Eq. (9)]. The distribution of lateral forces along the height of the structure is given by

$$F_i = \frac{(V_b - F_t) z_i W_i}{\sum z_j W_j} \quad (14)$$

Figure 5 Design spectra according to IBC 2000.⁵

Table 2 Minimum Base Shear Coefficient S_{DS} According to IBC 2000

Site Class	Mapped Spectral Response Acceleration at Short Periods									
	S_{DS}	0.25 V_{min}/W (%)	S_{DS}	0.50 V_{min}/W (%)	S_{DS}	0.75 V_{min}/W (%)	S_{DS}	1.00 V_{min}/W (%)	S_{DS}	1.25 V_{min}/W (%)
A	0.133	0.587	0.267	1.173	0.40	1.76	0.533	2.347	0.667	2.933
B	0.167	0.733	0.333	1.467	0.50	2.20	0.667	2.933	0.833	3.667
C	0.200	0.880	0.440	1.760	0.55	2.42	0.667	2.933	0.833	3.667
D	0.267	1.173	0.467	2.053	0.60	2.64	0.733	3.227	0.833	3.667
E	0.417	1.833	0.567	2.493	0.60	2.64	0.600	2.640	—	—

The top force F_t is a simple way of accounting for the effect of higher modes on the force pattern and is important for tall buildings only.

4.2 Modal Analysis Procedures

For the purposes of seismic design the method is almost invariably applied in combination with the design response spectrum and is typically referred to as *modal response spectrum analysis*. Its field of applicability covers essentially cases where modes other than the fundamental one affect significantly the response of the structure. Detailed presentations of the modal response spectrum analysis can be found elsewhere.^{3,4,11} In modal analysis involving lumped mass systems, the (elastic) force vector \mathbf{f}_n for the n th mode, calculated on the basis of the response spectrum, is

$$\mathbf{f}_n = \mathbf{m}\boldsymbol{\varphi}_n \pi \Phi \frac{L_n}{M_n} S_{pan} \quad (15)$$

where \mathbf{m} is the mass matrix, $\boldsymbol{\varphi}_n$ is the n th mode shape vector, L_n is the earthquake excitation factor (depending on the mass distribution and the corresponding mode shape), M_n is the generalized mass, and S_{pan} is the spectral pseudoacceleration corresponding to the period T_n of the n th mode. Note that the forces f_{in} are acting on the (lumped) masses m_i ; in the common case of buildings with floor diaphragms, m_i is the mass of the i th story and f_{in} the n th mode force acting on this mass. The corresponding maximum *base shear* for the n th mode is given by

$$V_{0n} = \frac{L_n^2}{M_n} S_{pan} \quad (16)$$

The *displacements* for the n th mode can be calculated from

$$\mathbf{u}_n = \boldsymbol{\varphi}_n \frac{L_n}{M_n \omega_n^2} S_{pan} \quad (17)$$

where $\omega_n = 2\pi/T_n$ is the circular frequency of the n th mode. Since the response of a structure results from the contribution of all modes, and since modal maxima generally do not occur simultaneously, it is customary to combine the action effects S_i from the individual modes in a statistical way. The most commonly adopted procedure is the *square root of the sum of squares* (SRSS) combination, that is,

$$S_{i,max} \cong \sqrt{S_{i1}^2 + S_{i2}^2 + S_{i3}^2 + \dots} \quad (18)$$

where $S_{i,max}$ is the probable maximum value of the action effect (force or displacement), and the subscripts 1, 2, 3, ... refer to the 1st, 2nd, 3rd, ... mode; a sufficient number of modes should be considered in estimating $S_{i,max}$. Equation (18) gives reasonable values in many practical cases but is generally unconservative when two or more modes are closely spaced, that is, their periods are close to each other; this is often the case in three-dimensional structures susceptible to torsional effects. In these cases more refined combination rules, such as the *complete quadratic combination* (CQC)¹² or a time-history analysis are appropriate.

4.3 Time-History Procedures

Time-history analysis is used for design purposes only as an exception and almost exclusively whenever non-linear effects are to be considered explicitly, rather than through the R -factor approach. When acceleration time histories are used for design, it is imperative that they actually correspond to the design earthquake for the site under consideration, which means that the envelope of the response spectra of the accelerograms used should reasonably match the *elastic* design spectrum for the site (no R -factor reduction). Several options are available for selecting a set of design accelerograms:

- Use of records from actual earthquakes, scaled to the design earthquake intensity
- Use of artificial accelerograms generated so as to match the (target) elastic response spectrum; this is sometimes referred to as the *engineering method*
- Use of simulated accelerograms generated by modeling the source and travel path mechanisms of the design earthquake (*seismological method*).

Selection of Recorded Accelerograms This can be the ideal solution whenever an extensive database of acceleration time histories is available, containing records from earthquakes with a broad range of characteristics. Then, a selection can be made of records matching the source parameters (focal mechanism and depth, distance from source), travel path, magnitude, peak ground motion parameters (A, V, D), and duration, for the site under consideration. In a practical context, the criteria for selecting ground motion

records are often related to the use of the A/V (i.e., peak ground acceleration over peak ground velocity, PGA/PGV) ratio,¹³ which is a simple parameter, easy to calculate, and correlates well with the M–R (magnitude–distance) relationship as well as with the site conditions. Another possible criterion is to select ground motion records whose spectra (S_{pa} or, preferably, S_{pv}) are peaking in the vicinity of the fundamental period of the structure under consideration, irrespective of their other characteristics.

Scaling of Recorded Accelerograms The most commonly applied scaling procedure is based on the PGA, that is, all records used for design are scaled to the same PGA but, as discussed in Section 3, the spectral ordinates are proportional to the PGA over the short period range only ($T < 0.2$ s), whereas for longer periods (covering most of the usual civil engineering structures) they are proportional to the PGV, and for very long periods ($T > 3.0$ s) they are proportional to the peak ground displacement (PGD). All these values are ground motion dependent only, that is, they are not correlated in any way to the characteristics of the structure to be designed.

A sensible choice of scaling parameters accounting for the characteristics of both the record and the structure are the spectral values, either those of the response spectrum or of the Fourier spectrum. An early (1952), but still quite popular, proposal is Housner's¹⁴ *spectrum intensity*, SI_v , which is the area under the S_{pv} spectrum

$$SI_v = \int_{T_a}^{T_b} S_{pv}(T, \xi) dT \quad (19)$$

with $T_a = 0.1$ s, $T_b = 2.5$ s, and $\zeta = 20\%$. The reason for selecting these period limits is that they were deemed to represent the range of typical periods of buildings at the time; it is understood that SI_v is intended to be an overall measure of the “damageability” of a ground motion with respect to a population of structures. Whenever a particular structure is to be designed or assessed, a condensation of the limits suggested by Housner is appropriate. Kappos¹⁵ suggested a modified Housner intensity based on $T_a = 0.8T_1$ and $T_b = 1.2T_1$, where T_1 is the fundamental period of the structure, calculated using the average of the SI values from the 5 and 10% velocity spectra.

Use of Simulated Ground Motions In the engineering method, artificial accelerograms are generated so as to match the (target) elastic response spectrum, hence they are typically called *spectrum-compatible motions*. In the seismological method, simulated accelerograms are generated by modeling the source and travel path mechanisms. All the aforementioned types of accelerograms are generally allowed as input for time-history analysis in *Eurocode 8*,⁶ which, however, appears to promote the first. The duration of the records must be consistent with the characteristics (M, R, etc.) of the earthquake underlying the establishment of the design α_g . A minimum

of five records is required for time-history analysis and additional rules are given in *Eurocode 8*,⁶ regarding the allowable difference between the mean spectrum of these records and the code spectrum. IBC, on the other hand, recommends⁵ the use of actual recorded accelerograms as input for time-history analysis; these should be selected from at least three different events, with due consideration of magnitude, source distance, and mechanisms, that should be consistent with the design earthquake. Simulated time histories are allowed whenever three appropriate recorded motions are not available. The design is based on the maximum response when three motions are used, while an average value can be used when the accelerograms used exceed seven.

5 DESIGN EXAMPLE

Consider the three-story, four-bay, moment resisting R/C frame building shown in Fig. 6, for which the base shear and its distribution along the height is to be determined. For such a frame, an approximate value for the fundamental period is given in *Eurocode 8*:⁶

$$T_1 = 0.075h^{3/4}$$

hence for $h = 10.5$ m $\Rightarrow T_1 = 0.44$ s.

The above approximate period value corresponds to the plateau ($T_B < T < T_C$) of the elastic [see Eq.(8)], as well as of the design, spectrum given by *Eurocode 8*⁶ for subsoil class B and corner periods: $T_B = 0.15$, $T_C = 0.50$. Hence, the ordinate of the design spectrum can be calculated as follows:

$$S_d(T) = a_g S \frac{\beta_0}{q} = 0.24g \times 1.0 \times 2.5/3.9 = 0.153g$$

where a_g = effective peak ground acceleration
= 0.24g

S = soil parameter, which for the (assumed) subsoil class B is equal to 1.0

$\beta_0 = 2.5$

q = behavior factor = $q_0 K_W = 3.9 \times 1.0 = 3.9 > 1.50$

q_0 = basic value of the behavior factor, dependent on the type of the structural system and on regularity in elevation
= $3.0\alpha_u/\alpha_1 = 3.9$ (for a frame system and ductility class M, according to Table 5.1 of *Eurocode 8*)

$\alpha_u/\alpha_1 = 1.30$ for a multistory, multibay frame

K_W = factor reflecting the prevailing failure mode in structural systems with walls
= 1.0 for a frame system

The *total base shear* that acts on the frame is a function of its weight and is therefore derived as

$$V_b = S_d(T_1)W = 0.153g \times (3 \times 300) = 137.7 \text{ kN}$$

The *lateral forces* corresponding to the calculated base shear are derived according to (10), assuming that

Figure 6 Calculation of the equivalent seismic forces of an RC frame.

the fundamental mode is increasing linearly with the building height, hence s_k are substituted by h_k , the heights of stories above the foundation level. As a result, Eq. (10) can be written as

$$F_i = V_b \frac{h_i W_i}{\sum h_j W_j}$$

and the forces F_i (as calculated in Table 3 and shown in Fig. 6) can then be used for a standard static analysis of the building.

6 CONCLUDING REMARKS

The goal of this chapter was to first present some fundamentals of earthquake engineering and then focus on different methods for the dynamic analysis of structures subjected to earthquakes. Subsequently, the most important features of *seismic design* (i.e., design of structures against earthquakes) were outlined, focusing on practical aspects of design regulations. However, since the scope of this short chapter was inevitably limited, the reader should make recourse to the more specialized literature (such as Chopra¹¹ and Kappos¹⁶) for a more detailed treatment of seismic analysis and design.

Table 3 Lateral Forces Acting on the Selected Frame

Story Level	W_i (kN)	h_i (m)	$h_i W_i$	F_i
0		0	0	
1	300	4.5	1350	27.54 kN
2	300	7.5	2250	45.90 kN
3	300	10.5	3150	64.26 kN
			6750	137.70 kN

CHAPTER 118

LOW-FREQUENCY SOUND TRANSMISSION BETWEEN ADJACENT DWELLINGS

1 INTRODUCTION

Low-frequency sound transmission between adjacent dwellings is causing an increase in noise nuisance. Reasons for this are the proliferation of hi-fi and home movie systems of high power and enhanced bass response and increased use of mechanical services in residential buildings and appliances within dwellings. Many of these sources generate significant low-frequency sound. In general, building elements that fail to satisfy sound insulation requirements and regulations do so at low frequencies. Lightweight cavity walls, for timber-frame housing and conversions, are least effective at low frequencies. Masonry walls and floors often fail in the frequency range of 50 to 400 Hz.

A major limitation in the implementation of present standard methods of test and prediction of wall and floor insulation at low frequencies results from the modal characteristic of the sound pressure fields generated in the rooms and of the vibration fields on the separating walls and floors. This causes large spatial and spectral variations in sound pressure level and the sound pressure level difference between rooms is strongly dependent on the room size and shape.

The standard methods for the measurement and prediction of sound insulation between dwellings should include a correction for the modal characteristics of the sound fields at low frequencies. Heavyweight and lightweight constructions must be treated differently and yield different corrections to the standard relationship between sound pressure level difference and sound reduction index.

2 LABORATORY AND FIELD PERFORMANCE INDICES

Although there has been a proliferation of sources of low-frequency noise in buildings,^{1,2} the current standards³⁻⁶ deal only with the frequency range of 100 to 3150 Hz. An annex to the International organization for Standardization (ISO) 140 standard for laboratory and field measurements deals with frequencies down to 50 Hz, but there is poor reproducibility

between laboratories below 100 Hz and a method of measurement has yet to be agreed. Eventually, it may be possible to achieve good reproducibility between laboratories using a universally acceptable measure of sound reduction index for frequencies below 100 Hz.⁷ However, a fundamental question remains on how such laboratory measurements can be related to field performance of the separating wall, floor, or partition when in situ. Diffuse or neutral acoustic field conditions in test chambers do not correspond to the modal behavior of sound fields in small room volumes associated with dwellings at low frequencies.⁸

The standard expression for sound reduction index R , in laboratory test conditions, is⁴

$$R = (L_1 - L_2) + 10 \log(S/A_2) \text{ dB} \quad (1)$$

where L_1 and L_2 is the average sound pressure level in the source and receiver rooms, respectively, S is the party wall area, and A_2 is the total absorption of the receiving room. The performance of a partition in field conditions is given by the standardized level difference⁵:

$$D_{nT} = (L_1 - L_2) + 10 \log(T/0.5) \text{ dB} \quad (2)$$

where T is the reverberation time of the receiving room.

Procedures now are in place to relate the field performance of walls and floors to the laboratory measurements, including the effects of flanking transmission.⁹ However, the relationships are based on the assumption of diffuse sound field conditions in the rooms. The sound fields in small rooms, at low frequencies, are not diffuse and exhibit large variations with source and receiver position and frequency. The maxima and minima in sound pressure level, at the room resonances, also are accentuated because room surfaces and contents are less effective absorbers at low frequencies than at mid and high frequencies.¹⁰

Figure 1 Measured (heavy line) and finite element model predicted (light line) sound pressure level in a room of plastered brick walls and concrete floor and ceiling.

3 SOUND FIELDS IN ROOMS AT LOW FREQUENCIES

In addition to laboratory and field measurements, theoretical modal analysis and finite element methods have been used to demonstrate that the room dimensions exert a strong influence on sound pressure level difference between rooms at low frequencies.^{11–13} Adjacent rooms of identical shape and size and thus of the same resonance frequencies are strongly acoustically coupled, and the resultant sound pressure level difference can deviate from the value, which would be obtained in diffuse field conditions.

For a rectangular room with hard walls, the sound pressure can be expressed in terms of normal modes¹⁴:

$$p = p_0 \cos \left[\frac{\pi n_x x}{L_x} \right] \cos \left[\frac{\pi n_y y}{L_y} \right] \cos \left[\frac{\pi n_z z}{L_z} \right] \quad (3)$$

for $0 \leq x \leq L_x$, $0 \leq y \leq L_y$, $0 \leq z \leq L_z$ where n_x , n_y , n_z are integers and p_0 is the maximum pressure amplitude. The natural frequencies are given by

$$f_{n_x n_y n_z} = \left(\frac{c}{2} \right) \left[\left(\frac{n_x}{L_x} \right)^2 + \left(\frac{n_y}{L_y} \right)^2 + \left(\frac{n_z}{L_z} \right)^2 \right]^{1/2} \quad (4)$$

where c is the velocity of sound.

In Figure 1 is shown the measured and predicted sound pressure level at one position in a rectangular ($5.75 \times 4.88 \times 4.24$ m) chamber with a loudspeaker in a corner. The chamber is of plastered brick walls and concrete floor and ceiling. The peaks and dips are accentuated because of the low room absorption below 200 Hz. The predicted response was obtained from a finite element model,¹⁵ which gave best agreement with measurement on assuming an average absorption coefficient of 0.02. The chamber volume of 120 m³ is

typical of acoustical test chambers, designed to give an even distribution of room modes and high modal density (see room modes indicated in Fig. 1) in order to approximate a diffuse field condition necessary for standard tests.

Rooms in dwellings generally are of small dimensions, and the sound field has a low modal density at frequencies below 200 Hz. In Figure 2 is the measured and predicted sound pressure level at one position in a room ($4.24 \times 2.84 \times 2.40$ m) with a loudspeaker in a corner. The room modes are more separated than in the previous case (see room modes indicated in Fig. 2) with fluctuations in sound pressure level of the order of ± 10 dB about the average value. The room was constructed of plasterboard and timber-frame walls, timber floor, and ceiling. The finite element model prediction gives best agreement with measurement with an assumed average absorption coefficient of 0.15. This is because the lightweight construction acts partially as panel absorbers below 200 Hz and room damping is by modal reaction rather than local reaction.¹⁶ In general, it has been found that the absorption of room contents, such as furnishing, has little effect on the spatial and spectral variation of sound pressure level at low frequencies.¹⁰ Again, this is because porous absorbers are inefficient at low frequencies and also interact less with normal room modes than with tangential and oblique modes, which come into play at higher frequencies.

4 BENDING FIELDS ON WALLS AT LOW FREQUENCIES

So far, we have described the sound pressure field in a room in terms of normal modes as a prelude to discussing the modal interaction between two adjacent rooms. The generated bending field, on the wall separating the two rooms, also interacts with the room pressure fields. The bending wave field also can be expressed in terms of normal modes. If the wall is

Figure 2 Measured (heavy line) and predicted (light line) sound pressure level in a room of timber-frame walls and timber floor and ceiling.

Figure 3 Measured and predicted sound pressure level difference of a lightweight cavity wall.

modeled as a simply supported plate with bending stiffness $B = Eh^3/12(1 - \nu^2)$ where E is Young's modulus and ν is Poisson's ratio, then the bending vibration field takes the form¹⁷

$$v(y, z) = v_{n_y n_z} \sin(L_y/\pi n_y y) \sin(L_z/\pi n_z z) \quad (5)$$

$v_{n_y n_z}$ is the bending vibration amplitude, L_y and L_z are the wall dimensions, n_y , n_z are integers, and $0 \leq y \leq L_y$, $0 \leq z \leq L_z$. The natural frequencies of the wall are given by

$$f_{n_y n_z} = \frac{\pi}{2} \left(\frac{B}{\rho_s} \right)^{1/2} \left[\left(\frac{n_y}{L_y} \right)^2 + \left(\frac{n_z}{L_z} \right)^2 \right] \quad (6)$$

where ρ_s is the mass per unit area. If the natural frequencies of the wall bending field coincide with

those of the room pressure fields, then large variations in sound pressure level difference can be expected.

5 INTERACTION BETWEEN ROOM MODES AND WITH WALL MODES

Field surveys of low-frequency sound transmission across lightweight cavity walls and heavyweight masonry walls indicate large spatial and spectral variations in level difference. Figure 3 shows the measured and finite element model predicted one-third octave band sound pressure level difference across a lightweight cavity wall of area 2.84×2.4 m. The wall was constructed from two leaves of 38-mm plasterboard, each on 50-mm timber frames and separated by a 200-mm cavity containing 50-mm mineral wool. The separated rooms were of equal

Figure 4 Measured and predicted sound pressure level difference of a heavyweight cavity wall.

dimensions— $4.23 \times 2.84 \times 2.4$ m—and therefore had the same room modes, which are shown in Fig. 3.

Both predicted and measured curves indicate a dip at 40 Hz, which is caused by the acoustic-acoustic coupling of the (1,0,0) mode in each room. Preliminary checks were made of the theoretical mass-spring-mass frequency f_{msm} . For the case shown, $f_{msm} = 48$ Hz and did not coincide with the room mode coupling frequencies. In general, the mass-spring-mass resonance appeared to have little influence on room mode coupling. Also indicated in Fig. 3 are the wall modes, which onset at 20 Hz, below the first room modes. The wall modal density is relatively high, even below 100 Hz, and no single wall mode strongly influences room mode coupling.

Figure 4 shows the measured and finite element model predicted one-third octave band sound pressure level difference across a heavyweight cavity wall of area 3.88×2.38 m. The wall was constructed from two leaves of 140-mm plastered brickwork, separated by a 75-mm cavity. The two rooms were of equal dimensions, $2.7 \times 3.88 \times 2.38$ m. In the case shown

in Fig. 4, a significant dip in level difference occurs in the 63-Hz band, which is caused by the coupling of the room modes perpendicular to the separating wall [in this case the (0,1,0) modes], which also are in close proximity to the first (1,1) wall mode.

6 STATISTICAL SURVEY OF THE EFFECT OF ROOM DIMENSIONS

A field measurement survey of the influence of room dimensions on sound pressure level difference between rooms at low frequencies would be protracted and expensive. The survey would involve recording the room dimensions, construction details, location of loudspeakers, and microphone positions, and measurements would require a more refined frequency analysis than is presently available to the standard methods. However, an experimentally validated numerical model (in this discussion, a finite element model) of sound transmission between adjacent rooms can be employed in a survey of different room sizes, which allows the salient features to be identified and yields the likely statistical distributions.

Figure 5 Sound pressure level difference of a lightweight cavity wall of plasterboard on timber frame of 3.5×2.5 -m area for room volumes in the range of 20 m^3 to 50 m^3 .

Figure 6 Sound pressure level difference of a 3.5×2.5 -m heavyweight wall for room volumes in the range of 20 m^3 to 50 m^3 .

Figure 7 Average sound pressure level difference and standard deviation for a lightweight cavity wall (lower curve) and a heavyweight wall (upper curve), between equal rooms for volumes ranging from 25 m^3 to 50 m^3 .

In Figure 5 are shown the predicted spatial average sound pressure level difference for a lightweight cavity wall of plasterboard on timber frame, between equal rooms where the room volumes have been varied from 20 to 50 m^3 . The separating wall area is constant at $3.5 \times 2.5 \text{ m}$, and the room volumes were varied by altering the room dimension perpendicular to the separating wall (i.e., from 2.3 to 5.7 m).

There are some dips in sound pressure level difference in the 50 -Hz third octave band and also in the 80 -Hz band, which correspond to the normal room modes perpendicular to the party wall. However, there are also some peaks in the 80 - and 125 -Hz band and, in general, the adverse dips are not pronounced because the wall modal densities are high and no single wall mode predominates.

In Figure 6 are shown results for the case of a heavyweight wall, of the same area and for the same range of room volumes. Here the variation in sound pressure level difference is much greater than for the

lightweight wall due to matching of both the room modes and the wall modes. The wall modes are few in number and therefore can be influential.

Figure 7 shows the mean sound pressure level difference and standard deviation for the two wall types: lightweight cavity and solid masonry. The values were obtained from 100 room pairs, ranging in volume from 25 to 50 m^3 . The sound pressure level difference across lightweight cavity constructions shows a mass law trend with little statistical spread due to the effect of room volume. The standard deviation is of the order of 2 to 3 dB . This means that, although dips occur in sound pressure level difference, at frequencies dictated by the normal room modes perpendicular to the wall, they are of the order of 5 to 10 dB and “wash out” when all room volumes are considered in the population. Overall, the average sound insulation of a party wall of lightweight construction is lower than that of the heavyweight construction, below 200 Hz , as expected.

The sound pressure level difference across heavyweight walls is little affected by variations in room volume at frequencies below the onset of the first wall mode; in this case, below 50 Hz. Above this frequency, the sound pressure level difference is strongly dependent on room modes and thus on room dimensions, and the fluctuations are accentuated by the wall modes, which are well spaced in frequency. For the case considered, a 200 mm masonry wall, the standard deviation is 12 to 15 dB in the frequency range of 50 to 125 Hz.

7 PRACTICAL CONSIDERATIONS

Architects and builders naturally would be interested to know if dips in sound pressure level difference at low frequency could be predicted and possibly avoided. Such a prediction might be given as a correction to the standard relationship between sound pressure level difference and sound reduction index, expressed as a function of the room and wall modal distributions, in particular of the simultaneous occurrence of room and wall modes in the measurement band of interest.

However, the corrections should be simple. This is possible if the following is assumed: A standard laboratory method of measuring sound reduction index is possible for the frequency range of 50 to 100 Hz; the adjacent dwellings consist of rectangular room pairs of the same dimensions; the separating wall can be characterized as either lightweight cavity or heavyweight masonry; the associated flanking walls and floors are assumed to be of the same construction as the separating wall.

The first step is to estimate the third octave frequency band $f_{1/3}$ where the dip in sound pressure level difference is likely to occur due to the coupling of room modes. This is when $f_{1/3} = c/(2L)$, where L is the room length perpendicular to the separating wall. It is not straightforward to estimate the natural frequencies of the wall bending vibration since the modes are strongly dependent on edge conditions, which cannot easily be assessed. The second step, therefore, assumes a worst-case condition, where a wall mode also occurs in the band $f_{1/3}$ described above. A basic construction type is established, heavyweight or lightweight cavity, and the area of the separating wall also is considered.

For heavyweight walls of area less than 10 m², subtract 20 dB from the value of level difference as follows:

$$L_1 - L_2 = R - 10 \log[S/(\alpha S_T)] - 20 \text{ dB} \quad (7)$$

where S is the wall area, S_T is the total room area, and $\alpha = 0.02$. For heavyweight walls of area greater than 10 m², the correction to Eq. (7) is -10 dB. For lightweight cavity constructions, the correction to Eq. (7) is -5 dB, with $\alpha = 0.15$, irrespective of wall size.

Architects and builders should avoid pairing rooms of equal dimensions, if possible. The room dimensions perpendicular to the separating wall should differ by 0.5 to 1.0 m. It also is recommended that heavyweight walls should not be smaller than 10 m². Where possible, the room shapes should be nonrectangular. These

recommendations will not eliminate low-frequency dips (and peaks) in sound pressure level difference between adjacent rooms but will reduce the variation in sound insulation by reducing the strength of the acoustic coupling between room modes and between room and wall modes.

PART XI

COMMUNITY AND ENVIRONMENTAL NOISE AND VIBRATION PREDICTION AND CONTROL

CHAPTER 119

INTRODUCTION TO COMMUNITY NOISE AND VIBRATION PREDICTION AND CONTROL

Malcolm J. Crocker

Department of Mechanical Engineering

Auburn University

Auburn, Alabama

1 INTRODUCTION

The main sources of urban community noise are (a) road traffic, that is, trucks, cars, and motorcycles, (b) aircraft/airport noise, (c) railroads, (d) construction noise, (e) noise from light and heavy industry, and (f) noise from recreation activities. Road traffic noise is the most important of these and is discussed in this chapter in some detail. Aircraft/airport noise, although often cited as a major problem, is generally considered to be of less importance because, although it can be intense, it is mostly concentrated around major airports. However, from another point of view, aircraft noise is of extreme importance since strong public resistance to airport expansion in many countries is driven by aircraft noise complaints around airports. Railroad noise is a problem for residential strips situated along major rail lines, but it is much less pervasive than road traffic noise. Construction noise is often a problem too since in large cities there are normally some new building projects being undertaken; in addition, noise from the construction of new highways is a concern where heavy equipment contributes to the noise problem.

2 DISCUSSION

Several noise indicators and rating measures are in use. The equivalent sound pressure level L_{eq} is used in many countries for the assessment of road traffic noise, although the statistical 10% level L_{10} remains in use in Australia, Hong Kong, and the United Kingdom for target values and insulation regulations for new roads and planning values for new residential areas. The A-weighted day–night average sound pressure level, DNL is currently the main descriptor of community noise in the United States. With DNL, a penalty of 10 dB is added to noise made at night. In Europe the day–evening–night sound pressure level, LDEN is widely used. With LDEN, penalties of 5 dB are applied to noise in the evening and 10 dB at night. Chapter 34 discusses some of the descriptors that have been used. Chapter 127 describes the current practice of evaluating community noise problems in Europe, the United States, and several other countries. Coelho has written a review of community noise in Chapter 130 in which the different types of community noise ordinances are described.

In the United States, the day–night average sound pressure level (DNL) has been in widespread use to assess community noise annoyance since its adoption

by several federal agencies in the mid-1970s. If the DNL of the community noise is below 70 dB, there is little danger of hearing loss. However, many people become highly annoyed, and there can be significant sleep disturbance in the community. In 1978, by evaluating the results of 11 clustering social surveys on noise annoyance in several countries, Schultz produced a curve relating the average annoyance response percentage of people highly annoyed with the day–night sound pressure level. See Fig. 1. The Schultz curve has been widely used since then, although in recent years considerable doubt has been expressed whether it can be applied with equal confidence to different sources of community noise, including road traffic, railroad, and aircraft.

As shown in Fig. 18 of Chapter 34, later studies sponsored by the U.S. Air Force in the early 1990s have indicated that people have a moderate, but a different, reaction to aircraft, traffic, and railway noise at the same day–night average sound pressure level.²

Figure 1 Synthesis of all the clustering survey results. The mean of the “clustering surveys” data, shown here, is proposed as the best currently available estimate of public annoyance due to transportation noise of all kinds. It may also be applicable to community noise of other kinds.¹

Figure 2 Percentage highly annoyed persons (%HA) as a function of DNL. Two synthesis curves per mode of transportation, and the data points are shown. For the curves obtained with multilevel analysis the 95% confidence intervals are shown.³

One possible explanation may be that aircraft noise near a busy airport has a greater variation in level in time and has a different frequency content (generally higher) than road or rail traffic. Another explanation may be the inadequacy of the day–night sound pressure level measure itself, which does not make any allowance for level or, even more importantly, for loudness.

In a more recent study, Miedema and Vos³ came to a similar conclusion as Finegold et al.,² although their results were slightly different in magnitude. At high values of DNL between 60 to 70 dB, the ranking of road traffic and railway noise differ a little from the earlier results of Finegold et al.² Their conclusions may be summarized as follows. Below a DNL of 40 to 45 dB, virtually no one is highly annoyed (HA). As the DNL increases, so does the percentage of the population who are highly annoyed (%HA). The rate of increase in the %HA is greater for aircraft noise than road traffic noise, which in turn has a greater rate of increase than railway noise.³ Some of the results of this study are given in Fig. 2, which shows curves fitted to the data points by a least squares regression procedure. Since the 95% confidence limits for the three curves do not overlap, for the higher levels of DNL it can be concluded that the percentage of people that are highly annoyed, %HA, depends on the mode of transportation causing the noise.³

Equations fitting the data,³ assuming zero annoyance at an A-weighted sound pressure level of 42 dB, are

$$\begin{aligned} \text{Aircraft : } \%HA &= 0.20(\text{DNL} - 42) \\ &\quad + 0.0561(\text{DNL} - 42)^2 \\ \text{Road traffic : } \%HA &= 0.24(\text{DNL} - 42) \\ &\quad + 0.0277(\text{DNL} - 42)^2 \\ \text{Rail : } \%HA &= 0.28(\text{DNL} - 42) \\ &\quad + 0.0085(\text{DNL} - 42)^2 \end{aligned}$$

More recently Fidel and Silvati have also found that aircraft noise is more annoying than noise from other forms of transportation at the same values of DNL.⁴ In this study, the authors find 14% highly annoyed by aircraft noise at DNL of 55 dB and 5% highly annoyed at DNL of 50 dB, so that they estimate that the airport attitudinal survey data, when grouped in 5-dB wide “bins,” will yield 12% highly annoyed at about 54 dB.⁴ As a result of these and other more recent studies, many standards that continue to use A-weighted metrics such as LEQ, DNL, and LDEN have applied various penalties for aircraft noise in using the original Schultz curve (Fig. 1). The ISO standard⁵ applies a 3- to 6-dB penalty, while the American National Standards Institute (ANSI) standard uses a 5-dB penalty.⁶ The ANSI penalty is phased in between 55 and 60 dB as shown in Table 1.

Schomer et al. have questioned the continuing use of metrics such as DNL, which are based on A-weighting.^{7,8} It is well known that the A-weighting filter is independent of the sound pressure level, while the apparent loudness of the sound is not. Since annoyance is obviously related strongly to loudness, then use of metrics based on A-weighting are likewise fraught with problems. Schomer et al.⁸ have suggested instead that consideration should be given to the use of a loudness-level-weighted sound

exposure level (LLSEL) and loudness-level-weighted equivalent level (LL-LEQ). They suggest that LLSEL and LL-LEQ can be used to assess the annoyance of environmental noise. They conclude from their annoyance studies that, compared with A-weighting, loudness-level weighting better orders and assesses transportation noise sources, and with the addition of a 12-dB adjustment, loudness-level weighting better orders and assesses highly impulsive sounds. Thus, they state that significant improvements can be made to the measurement and assessment of environmental noise without resorting to the large number of adjustments that are required when assessing sound using just the A-weighting.⁸ Implementation of LLSEL and LL-LEQ capabilities on type 1, hand-held one-third octave band sound level meters would also be inexpensive.⁸

Some community noise ordinances and test codes or standards, such as those used to evaluate building site noise in Germany and the United Kingdom, require the intrusive noise to be compared with the ambient noise. If the noise is more than 10 dB above the ambient, it is deemed excessive, while if it is only 5 dB above, it may be tolerated. Fields claims that such a procedure is not supported by large amounts of noise data and surveys.⁹ According to Fields, the results of 70,000 evaluations of 51 noise sources by over 45,000 residents show that there is no evidence to support the long-held assumption that the reactions of residents in a community to an intrusive noise is reduced when there are other environmental noises present.⁹ In fact, Fields asserts that provided residents are able to ascertain a logical estimate of their long-term exposure to the actual noise levels of the intrusive events, the presence or absence of ambient noise does not affect their judgment of the amount of noise annoyance produced by the intrusive noise events.⁹ This is an important finding since it suggests that noise limits should be given as an absolute number of decibels, rather than an amount exceeding the ambient noise. Of course, if DNL or the new European LDEN is used as the noise limit, different limits must be set for aircraft, road traffic, and railway noise.

3 TRAFFIC NOISE PREDICTION AND CONTROL

There are several reasons for the emergence of traffic noise as the main source of community noise annoyance in most developed countries. The power-weight ratio of trucks and cars has been constantly increased to permit higher payloads and more speed and acceleration; the resulting higher power engines are usually noisier than the earlier lower power ones. The number of vehicles has increased dramatically in most countries over the last 20 or 30 years. This, combined with the movement of people from country to city and the natural increase in urban population, has exposed more and more people to more and more traffic noise. Chapter 120 discusses road traffic noise in more detail.

Although aircraft noise near airports is more intense than road traffic noise, the large number of vehicles in use and the fact that traffic noise is created in close proximity to residential housing ensures that it is a greater problem than aircraft and airport noise in most countries. The numbers of vehicles in use continues to increase. Studies in North America and Europe suggest that the external noise of many vehicles has not been significantly reduced in recent years. See Fig. 3, which shows the cruise-by noise levels of cars, light trucks, and heavy trucks over the period of 1974 to 1999.

The main sources on vehicles include power plant (and power train) noise, tire-road interaction noise, and wind noise. The noise of cars is dominated by tire noise, except under accelerating conditions at low speed, during which power plant noise exceeds tire noise. With medium and heavy trucks, however, power plant noise is not exceeded normally until about 40 km/h or 50 km/h is reached. At very high speeds wind noise on cars and trucks can become a major source, but below about 130 km/h it normally does not exceed tire noise. See Chapters 83, 86, and 87.

The sound pressure levels generated by heavy vehicles exceed those of most cars by about 10 to 15 dB. See Fig. 4. Trucks are vastly outnumbered by

Figure 3 A-weighted sound pressure levels of cars and light and heavy trucks measured at different speeds in 1974 and 1999.¹⁰

Figure 4 Cruise by exterior A-weighted sound pressure levels measured at 7.5 m for cars, heavy vehicles with two axles, and vehicles with more than two axles.¹¹

cars, but since they are normally in service for much longer periods than cars each day and they are so much noisier, they are a very important contributor to the overall road traffic noise problem. Noise levels near highways depend upon traffic flow rates and the mix of light and heavy vehicles with cars. Traffic noise tends to increase during mornings and evenings as people travel back and forth to work and other activities. Traffic noise is normally at a minimum during nighttime hours between about 1:00 and 4:00 a.m.

There are two main methods of evaluating vehicle noise. The first consists of measuring the passby noise of a vehicle at 7.5 or 15 m from the road centerline. The maximum A-weighted sound pressure level is recorded for single vehicles under controlled conditions normally on a special test track. See Chapter 120. Figure 4 is an example of the noise of individual vehicles traveling at constant speed, normally known as the “cruise-by” condition. For traffic noise prediction schemes, statistical passby measurements of randomly occurring vehicles are made near selected highways. The levels measured in the statistical passby approach are dependent on the mix of light and heavy vehicles with cars and are also dependent on the type of road surface.

The second type of test, normally used for regulatory purposes, consists of a full-throttle acceleration test performed on a vehicle, which approaches the measurement zone AA in Fig. 5 at a controlled speed. The measurement is again made at 7.5 or 15 m from the road centerline. The maximum A-weighted sound pressure level measured between lines A–A and B–B is recorded. See Fig. 5.

Traffic noise prediction schemes normally include statistical information on the numbers of vehicles, the vehicle mix, the noise characteristics of each vehicle, the road surfaces, and the shielding effects of

Figure 5 Measurement positions used for cruise-by or acceleration noise tests.

residential buildings on the propagation of the sound to the prediction points. See Chapter 120.

Community noise surveys and the creation of noise maps are used in communities as a basis for checking results of some of these traffic noise prediction schemes. Also traffic noise prediction schemes and community noise surveys of the one-octave, one-third octave, and/or A-weighted sound pressure level generated by traffic are useful in deciding on noise abatement strategies. The most common traffic noise

abatement strategy employed is the construction of roadside barriers, although porous sound-absorbent road surfaces are coming into use in some countries, as discussed in Chapters 83 and 86. See Chapter 58 for a general discussion on barrier performance and Chapter 122 for a discussion on their use to control road and rail noise in the community.

Although well-established prediction schemes are available to predict environmental noise from road traffic in communities, it has been demonstrated that specific prediction schemes can be established, which are more reliable for individual cities during workday hours. Of course, such specific prediction schemes cannot be transferred to other cities.¹² There are many other studies of road traffic noise and its prediction in the community.^{13–19}

4 RAIL SYSTEM NOISE PREDICTION AND CONTROL

Railway noise is generally less of a problem than road traffic noise and aircraft/airport noise. This is because the numbers of rail vehicles are much smaller than road vehicles, and railroad noise generally adversely affects smaller regions of most cities. Rail system noise is, however, a major problem for communities situated near railroad routes.^{20–30} The major sources on railway and rapid transit systems are (1) power plant noise, (2) wheel–rail interaction noise, and (3) aerodynamic noise. The main railway and rapid transit system power plants in use include (1) electric motors, (2) diesel engines, and (3) combined diesel–electric systems. See Chapter 121 for a detailed discussion on rail system noise sources and methods for their control.

Diesel power plants can be very noisy if the noise is not properly suppressed. Wheel–rail noise depends upon wheel–rail roughness and train speed. Wheel–rail roughness can be increased by the use of cast-iron brake systems. Disk brakes, which are coming into increasingly widespread use, have been found to reduce wheel–rail wear, roughness, and thus noise. Aerodynamic noise, although a problem inside rail vehicles at very high speeds, has not normally been found to be a major community noise problem, even at the very high speeds of 300 km/h as discussed in Chapter 121.

Community noise prediction schemes for railway noise must include data on the power plant and wheel–rail noise of the rail vehicles, the number of railcars in operation and the rail vehicle speeds. In addition, the prediction schemes must account for the attenuation caused by air and ground surface absorption and by the distance to the observation points. The screening caused by obstacles, including buildings, railway cuttings, embankments, and purpose-built noise barriers must also be included in the schemes. There is some evidence to suggest that railway noise causes less sleep disturbance than road traffic noise at the same noise level.^{26–31} In the United Kingdom, an A-weighted sound pressure level differential in favor of railway noise has been used in the development of railway noise legislation, using the equivalent A-weighted sound pressure level and existing road traffic noise legislation as the base. Railway noise and

its effects continue to attract the attention of many researchers and authorities.^{26–31}

5 ATTENUATION PROVIDED BY BARRIERS, EARTH BERMS, BUILDINGS, AND VEGETATION

Noise barriers are being used increasingly to protect residential communities from road traffic and rail and rapid transit noise. Chapter 58 describes empirical formulas that can be used to predict barrier performance. Barriers are of limited use to protect residential areas from aircraft and airport noise, and construction site noise, with the possible exception of their use to offer protection from the noise caused by the testing of aircraft engines during ground run up. Likewise, the mobility and elevation of noise sources of construction equipment used on building sites and highway construction sites often make the use of barriers of limited use. Urban barriers must also be designed to be acceptable aesthetically. The formulas for barrier performance given in Chapter 58 are mostly based on idealized theoretical considerations or experimental studies conducted in the laboratory. Chapter 122 describes some of the practical considerations in the use of urban barriers.

The attenuation of a barrier is normally defined in two main ways. The first involves the barrier *attenuation*, which is defined as the difference between the sound pressure levels measured (or predicted) at a location and the sound pressure level at the same location under free-field conditions. The second definition involves the reduction in sound pressure level (known as *insertion loss*) at the receiving location achieved by the *insertion* of the barrier. The attenuation provided by a barrier is a function of frequency. More exactly it can be related to the difference between the two path lengths from the source to the receiver divided by the wavelength: (1) over the barrier and (2) straight through the barrier. This quantity is known as the Fresnel number, which is also used in optics. See Chapter 58.

The Fresnel number can also be related to the effective nondimensionalized height parameter of the barrier (defined as the ratio of barrier height perpendicular to the incident sound divided by its wavelength.) The effective height of the barrier increases with wavelength and so does the barrier attenuation. This means that a barrier of fixed height is more effective in attenuating high-frequency sound, and stronger shadows are created for high-frequency sound than low-frequency sound. A similarity can be observed with the behavior of light since an obstacle produces a stronger shadow for short-wavelength (high-frequency) violet light than long-wavelength (low-frequency) red light. See Chapter 58 for further discussion on barrier acoustics.

Theoretically, noise barriers can be shown to provide the same attenuation if placed at the same distance from the source or from the receiver. In practice, however, as common with other passive noise control measures, their placement nearer to the source is usually more effective. This is because receivers, such as the upper regions of high-rise buildings, can extend in height above a barrier placed near to them,

and thus sound is not blocked from reaching them and they are thus not protected.³² However, single- or multiple-road and rail vehicles are normally located close to the ground, and barriers placed close to them block the sound better, which would otherwise be traveling to the multiple elevated receivers.

It is particularly important to ensure that barriers do not have holes or leaks that can degrade their performance and that they are constructed from material with an adequate transmission loss (sound reduction index) to sufficiently attenuate sound penetrating them and reaching the receivers directly in that manner. Urban barriers are sometimes made to absorb sound on the side facing the source so as to reduce the sound reflected back to the source. Care must then be made to ensure that the sound-absorbing material can survive the local environmental conditions and not become degraded too rapidly. Chapter 122 describes the use of sound-absorbing material with urban barriers. Chapter 58 presents formulas for predicting the attenuation of barriers, while Chapter 122 gives formulas and nomograms for predicting the attenuation of barriers used in urban situations. These formulas are now incorporated in commercial software. The sound attenuation of barriers with complicated shapes such as cantilever, parabolic barriers, or earth berms can now be predicted with boundary element method (BEM) approaches.

Unfortunately, when barriers are used in the field, the atmospheric effects of turbulence or wind and/or temperature gradients above the barriers normally degrade their attenuation and/or insertion loss performance. Chapter 122 describes factors that must be considered when barriers are used in practical situations to reduce road and rail traffic noise in the community. Wind is probably the main cause of the degradation of the acoustical performance of barriers. Wind has been found to have two main effects. First, the turbulence in the wind causes the sound waves to be scattered so that some of the sound energy propagates into the shadow zone behind the barrier. Second, wind gradients, which exhibit increasing wind speed with height above a barrier (with wind blowing in the same direction as the sound propagation), can bend the sound downward into the so-called shadow region of the barrier, thereby decreasing its attenuation. Temperature gradients in which the temperature increases with height (called temperature inversions) can have a similar effect in bending sound downward into the shadow zone behind a barrier. In practice, the attenuation of an urban barrier does not reach its theoretical value because of such environmental effects, and in real-use urban barriers normally have an upper attenuation limit of about 20 dB, unless they are of double construction, in which case the upper limit is about 25 dB. See Chapter 122.

6 GROUND-BORNE VIBRATION TRANSMISSION FROM ROAD AND RAIL SYSTEMS

Vibration generated by road and rail vehicles, some industrial enterprises, and building sites is transmitted through the ground and into buildings nearby.

Vibration at frequencies up to 200 to 250 Hz can be transmitted at distances as far as about 200 m from roads or railway lines. Vibration at higher frequencies tends to be attenuated more rapidly with distance. The vibration caused in the buildings results in floor and wall vibrations, the movement of household or office objects, the rattling of doors and windows, and indirectly as reradiated noise. Vibration is annoying to people at frequencies up to 50 or 100 Hz because various body organs resonate at low frequencies. For example, the stomach and other internal organs resonate in the region of 8 to 10 Hz, and the eyes and head resonate at frequencies of about 20 to 40 Hz. The chest wall cavity resonates in the range of 50 to 100 Hz. Chapter 123 discusses some of these phenomena in more detail. Damage to buildings from vibration is unusual, although there are some cases where construction of new highways or railway lines has not been allowed because of the fear that the vibration they would cause could damage ancient historical buildings. Vibration of the ground or building foundations is normally measured in the vertical direction with velocity or acceleration transducers such as accelerometers. The quantities usually recorded consist of the maximum velocity or acceleration levels. The levels are normally measured in one-third octave frequency bands, and each band is weighted according to human response to vibration. Chapter 123 describes the procedures for measurement and prediction of these quantities. The chapter also discusses human response to vibration and suggests suitable vibration limits.

The sources of ground vibration from road vehicles include passage of the vehicle wheels over road irregularities such as bumps and holes. With rail vehicles, the source mechanisms are related to the travel of the wheels over the rail, which causes periodic and random forces. The periodic forces are created by the passage of the wheels over the spatially periodic supports of the rails and any discontinuities located at rail joints. The broadband random vibration is caused by unevenness or roughness in the rail and wheel contours. At high speed, vibration can also be caused when the vehicle speed exceeds either the Rayleigh surface wave speed in the ground or the bending wave speed in the rails, as described in Chapter 123.

Vibration is transmitted through the ground by various wave mechanisms. The wave motion is quite complicated and consists of three main types: dilatational or pressure waves, equivolume or shear waves, and free surface or Rayleigh waves, as described in Chapter 123. The main methods of protecting buildings from ground vibration include reduction of vibration at the source, such as better road and rail maintenance, the use of softer suspension systems for road and rail vehicles, resiliently mounted and better maintained rail tracks, and grinding of the wheels and rails to reduce roughness. Other methods to protect buildings include base isolation of the buildings themselves, as is described in Chapter 124.

Models exist for predicting the propagation of ground vibration from road and rail traffic.^{33,34} The models are mainly different because of the different

input force mechanisms. With road vehicles, for the purpose of generating the wheel–road interface forces, the road itself can be considered to be rigid while the vehicle and its suspension are assumed to generate the dynamic forces in response to the road roughness. With rail vehicles, however, the excitation is different and is related to the unsprung mass of the wheel and axle combined with the mass of part of the rail system. Existing models range from mostly empirical to completely theoretical. Two-dimensional theoretical models are simpler but do not include the complete effects of fully three-dimensional models. Finite element (FEM) and coupled finite element/boundary element (FEM–BEM) models have been used and are becoming available in commercial software packages. Finite difference methods are also in use and have some advantages over FEM–BEM models since the computational code is simpler. Using those models to calculate absolute vibration level³⁵ requires significant modeling details. Greatest accuracy is achieved when making predictions of insertion loss, even with relatively simple models. See Chapters 123 and 124.

7 BASE ISOLATION OF BUILDINGS FOR CONTROL OF GROUND-BORNE VIBRATION

Road and rail traffic and some industrial and/or building operations cause ground vibration of a fairly continuous nature. Railways are usually the sources of most intense ground vibration since they often carry relatively heavy vehicles at high speeds, which results in significant rapidly created forces transmitted to the ground. Although it is possible to reduce the vibration at the source in some cases, there is some limit to the reduction that can be achieved economically.

When new buildings, particularly those of a sensitive nature, such as hospitals, auditoriums, and concert halls are to be constructed near to existing highways and railway lines, suppression of the building vibration and base isolation of the buildings themselves should be considered. See the discussion in Chapter 124. Some simple, relatively low cost measures are available for reducing building vibration, including (1) increasing the damping in the structure, (2) stiffening certain regions of the building to move natural frequencies away from forcing frequencies thereby avoiding resonances, and (3) the installation of floating floors in sensitive parts of the buildings.

In cases where the ground vibration is severe, such as where a building must be constructed near to a railway, it may be necessary to vibration isolate the complete building from the ground by means of base isolation, as described in Chapter 124. This may be essential only for sensitive buildings. The amount of vibration that is acceptable in the building will depend upon its use and other factors such as the duration and nature of the vibration. The principles of base isolation are similar to those used to protect buildings against earthquakes; however, the lower level of vibration experienced from road, rail, and some industrial sources compared with earthquakes, makes the design criteria somewhat different for each case studied. Each building design will be different

and building use, acceptable vibration limits, and other criteria will determine the design chosen. Typical isolation frequencies are in the range of 5 to 15 Hz.

There are two main types of isolators normally used for base isolation of buildings. These include (1) laminated rubber isolators and (2) helical steel spring isolators. The rubber isolators can either be made from natural rubber or from synthetic rubber. Steel spring isolators usually combine several helical springs in one unit. The rubber isolators normally have higher inherent damping than spring isolators. However, the spring isolators are sometimes made with additional damping elements to suppress internal coil resonances of the springs at high frequencies, and to limit vibration during the rapid vibration onset or vibration decay caused by passing trains or vehicles. Steel springs are expensive but can be manufactured to have precise stiffness values and long life. Rubber isolators are usually less expensive but have the drawback that they can be subject to degradation more rapidly than steel springs unless they are protected against any possible hostile environmental conditions, which could cause the degradation. If adequate protection is provided, however, rubber isolators can be made to have sufficient life in terms of both degradation and creep performance.

The design of vibration isolators is described in Chapters 54, 59, and 124. Their performance in buildings is normally measured in terms of the insertion loss they provide, as explained in Chapter 123, since this quantity describes the benefit obtained from the use of the isolators. Single-degree-of-freedom models are useful to give some approximate indication of the isolator performance, although building vibration is much more complicated, and more sophisticated vibration models must be used for better vibration predictions. With continuous excitation, which is almost steady state, such as is caused by passing trains, the vibration problem can be treated in the frequency domain. With some cases where the excitation is more impulsive in nature, such as is caused by some industrial applications, then a time-domain modeling approach is more convenient. More complicated building base models employ finite element methods. Studies on base isolations of buildings continue.^{36–42} Various software programs are available commercially to create such sophisticated building vibration models. In some cases, simple two-dimensional numerical models are used to reduce computational demands. Three-dimensional approaches are more suitable to obtain more accurate building models, as discussed in Chapter 124.

8 AIRCRAFT AND AIRPORT NOISE PREDICTION AND CONTROL

Air travel is projected to continue increasing in the foreseeable future. These increases will require the expansion of existing major airports and the creation of new airports. Airport expansion provokes public resistance because of the annoyance, speech interference, and sleep interference caused by aircraft noise in nearby residential districts. Aircraft noise is a much more localized problem than surface transportation noise since it is significant primarily

around major airports. Most of the noise energy is produced by the operations of scheduled airliners, the contribution of the large numbers of general aviation aircraft being relatively small. See Chapter 125.

The introduction of early pure jet passenger aircraft in the late 1950s brought much higher noise levels during both takeoff and landing than the piston engine airliners that they replaced. The majority of piston engine propeller-driven airliners have now been phased out of service, although twin-engine prop-jet aircraft continue to be used on many low-density, short-range routes. Jet aircraft operate at much higher cruising speeds than do propeller ones, and the aerodynamic configuration necessary for them to achieve these results in higher takeoff and landing speeds. Required runway length is normally greater with jet than propeller aircraft, partly as a consequence of these higher speeds, and partly because jet engine thrust is reduced when an aircraft is stationary or nearly so. This naturally brings the airport noise closer to residential communities. The generally large size and inertia of long-range passenger jet aircraft, and their greater throttle response times compared with those of piston engine propeller-driven aircraft, require them to use long approach paths, resulting in more extensive low-level flight over surrounding neighborhoods. Moreover, jet aircraft normally use considerable amounts of power on approach to counteract the drag of their high-lift devices. The noise produced by jet powered aircraft is primarily from their engines. The aerodynamic noise produced by the passage of the aircraft through the air (termed airframe noise) is still normally insignificant in comparison. See Chapter 9 for a discussion on airframe noise.

In the early 1960s, the first fanjet engines (also known as turbofans or bypass jets) entered service. Although developed mainly to improve fuel economy, the fanjet engines were quieter than the first pure jet (or turbojet) engines of the same thrust. A fanjet engine can be regarded as essentially a ducted prop-jet engine, in which the propeller (called the fan) is ducted to improve efficiency. All long-range airliners and many medium-range airliners are now powered by fanjet engines. Such fanjet engines mostly produce broadband noise from their high-speed jet exhausts during takeoff, although with lower power conditions during landing approach, the tonal whine produced by the compressor stages usually becomes prominent. At a distance of 5 km, the A-weighted sound pressure level during a jet aircraft takeoff is of the order of 60 dB to 65 dB and is sufficient to interfere with speech. See Chapters 22, 34, and 125. Current wide-body fanjets (e.g., Boeing 717, 737, 767, 777, and 787 and Airbus A-300/310, A-318, A-320, A-330/340, A-350, and A-380) have considerable noise control technology built into their engines and are much quieter than the early pure jet and fanjet aircraft.

Some airliners have been particularly designed to have quiet operational characteristics. The BAe 146, first introduced in the 1980s, was an early, very quiet, four-engine jet airliner, which has special high-lift devices giving it short takeoff and landing capabilities

that make it able to operate from very short runways at small downtown airports. It is able to operate from downtown airports such as those at Mönchengladbach, Aspen, and at the London City Airport (a converted dock). In May 2006 landing and takeoff tests at the London City Airport of the newer Airbus A-318 has shown it can also use this downtown airport. Following evaluations by Airbus, London City Airport, and the UK airworthiness authorities, in March 2006, these authorities granted the A-318 a steep landing approach certification that enabled the airport compatibility tests to take place. With its very low noise characteristics, the A-318 makes it possible for it to use downtown airports such as the one in downtown London.

As discussed in more detail in Chapter 125, propeller-driven airliners are used on some medium-range and most short-range routes, and such aircraft are almost exclusively powered by gas turbine engines. Such turboprop aircraft, as they are commonly known, mainly produce tonal noise instead of the broadband jet noise. The noise of propellers is quite directional and is mostly radiated in the propeller plane. Helicopters are less commonly used than jet and turboprop aircraft, but they can be quite noisy and produce A-weighted sound pressure levels of about 60 dB at 1 km. Like propeller aircraft, the helicopter blade noise is very directional and is created both by the main rotor and the high-speed tail rotor.

Aircraft noise is evaluated for two main reasons: (1) for certification purposes and (2) to monitor the noise around airports. For certification, the noise of individual aircraft is measured using the effective perceived noise level (EPNL). For monitoring noise at airports it is normal to use a measure that accounts for many aircraft movements and the time of day that the noise is produced. In the European Union a composite measure known as day-evening-night sound pressure level (LDEN) is used. See Chapters 1, 34, and 125. The LDEN includes components for daytime, evening, and nighttime hours. During the evening, a 5-dB penalty is applied and at night a 10-dB penalty.

Figure 6 shows the noise levels and spectra of a fanjet aircraft both for takeoff and approach. Figure 7 shows the measurement locations used for certification of aircraft according to FAR Part 36 noise standards. See Chapter 34. Research on evaluating aircraft and airport noise and community annoyance continues.^{44–55}

9 OFF-ROAD VEHICLE AND CONSTRUCTION EQUIPMENT EXTERIOR NOISE PREDICTION AND CONTROL

Off-road vehicles and heavy construction equipment are used for roadway and railway construction, earth moving and excavation, laying of pipes and cables, and construction of new buildings. They are responsible for high levels of environmental noise and cause annoyance, speech interference, and sleep disturbance in residential areas. In addition, there is the possibility they can cause hearing damage to people operating this equipment or people working in close proximity. A-weighted sound pressure levels can be as high as 75 to 90 dB at distances of 15 m. Sound pressure levels at

Figure 6 Noise levels and spectra of wide-body fanjet aircraft (e.g., the Boeing 747).⁴³

distances of several hundred metres can be of the order of 60 to 70 dB, which is above acceptable community noise limits.

The main noise sources on off-road vehicles and construction equipment consist of the engine, exhaust,

intake, cooling fans, and the tracked wheels. Mobile compressors are also significant noise contributors and are often used in conjunction with impulsive noise generators, such as pneumatic drills, cutters, and vibrating roller equipment.

Figure 7 Measurement locations for certification testing of aircraft to FAR Part 36 noise standards.

In Europe, off-road vehicles and heavy construction equipment are required to have product labels giving their sound power outputs. Noise emission limitations are set by an EEC Directive. In the United States such equipment noise output is governed by community noise ordinances or state regulations. Mobile compressors are one exception since their noise output is regulated by the U.S. Environmental Protection Agency (EPA). Other countries do not seem to have uniform approaches to regulate the noise of off-road vehicle and construction equipment.

As described in Chapter 126, in Europe the sound power output of such equipment must be provided by display of a label. The sound power is normally determined through measurements of the sound pressure level at discrete microphone locations on a hemispherical surface as described in International Organization for Standardization (ISO) standards. Alternatively, the sound power can be determined with the use of sound intensity equipment.

Off-road vehicles and heavy construction equipment can be divided into three main categories as discussed in Chapter 126: (1) wheeled vehicles, including excavators, loaders, and graders, with which the engine is the dominant noise source, (2) tracked vehicles, in which the track noise is comparable to the engine noise, and (3) vibration and impact generating tools, including pneumatic drills and vibrating rollers, in which the noise is generated by the tool itself and no engine is involved.

The exterior noise can be reduced by a combination of passive means, including enclosures, vibration isolators, use of the vibration damping materials, sound-absorbing materials, and baffles and barriers. Enclosures can be very effective, particularly if absorbing materials are used inside and they are properly sealed. Unfortunately, this is not always possible because of the heat buildup created by most items of machinery, in particular the engine. The use of inlet and exhaust mufflers is essential on such equipment. Chapters 85 and 126 describe the design and use of such mufflers. Sound-absorbing material is sometimes placed inside the mufflers, although the material can lose its effectiveness because of contamination with moisture and carbon particles. Normally, for such reasons reactive mufflers are preferred. Chapter 126 gives an example of noise reduction on a mobile compressor. Other examples of mobile compressor noise control are given in Chapter 54. Compressor noise is discussed in detail in Chapter 74. Efforts continue on reducing interior and exterior noise and vibration of off-road vehicles.⁵⁶⁻⁵⁸

10 ENVIRONMENTAL NOISE IMPACT ASSESSMENT

Environmental noise impact assessments (sometimes known also as environmental noise impact statements) are used to balance the negative noise impact of a proposed development versus the benefits that that development, such as a new highway, industrial development area or recreation facility, could bring to a nearby community.⁵⁹⁻⁶³ See Chapter 127.

Existing community noise exposure guidelines are consulted when preparing the assessments. These are based on the premise that there is a level of noise that is acceptable to the majority of the community. If this level is likely to be exceeded by a proposed development, appropriate mitigation measures need to be selected with due consideration of cost and technical feasibility. The mitigated noise impact is assessed for acceptability to the potentially affected community as well as the benefit of the development to the community as a whole. In Chapter 127 the terms *community noise* and *environmental noise* are used interchangeably.

11 INDUSTRIAL AND COMMERCIAL NOISE IN THE COMMUNITY

The annoyance produced by industrial and commercial noise is very similar to that produced by road traffic noise when the long-term energy equivalent sound pressure levels are the same.^{64–67} However, as explained in Chapter 128, in most countries industrial noise is treated differently from road traffic noise. As explained in Chapter 130, it is common now for a city to have different districts zoned for noise. Normally, industrial enterprises are located in special zones in the city. It is desirable for the industrial zones to be separated from zones for residential housing. The separation in distance must not be too great; otherwise people will be inconvenienced by having to travel a long way to work. But the industrial and residential zones must not be situated too close to each other either. The noise created in residential areas from the sources in the industrial zones is normally predicted on the basis of the sound power outputs from the different noise source components in the industrial zone.

As explained in Chapter 128, industrial and commercial noise sources can be divided into two main categories. The first category includes steady noise sources that have little variation in level and character during the day and night. The second category includes intermittent noise resulting from different industrial production cycles and caused by vehicles coming and going to the industrial and commercial areas. Steady noise containing pure-tone and impulsive components is generally found to be less acceptable in residential areas compared with steady noise of the same long-term equivalent sound pressure level. This is particularly true when steady noise contains pure-tone components below 90 Hz, as discussed in Chapter 128. Impulsive noise is also known to be more annoying than steady noise of the same equivalent sound pressure level.

Chapter 128 describes a procedure for predicting the sound pressure levels in residential areas, which is based on knowledge of the sound power output per unit area of the industrial operation. Included in the procedure are adjustments for wind effects on the noise propagation. Such sound pressure level predictions are valuable in deciding whether new industrial operations should be permitted near residential communities and/or residential developments should be allowed near existing industry. It is important to monitor the noise levels produced by the industrial and commercial operations and make comparisons with those that

are predicted. Also in order to avoid community complaints, it is important to inform the public in the residential areas of such noise monitoring and also to provide details about all activities being undertaken to reduce noise from the industrial and commercial zones reaching the residential areas.^{68–78}

12 CONSTRUCTION AND BUILDING SITE NOISE

Noise created on building sites in a city can interfere with speech, sleep, and other human activities.^{65–69} The noise created comes from a variety of machinery and mechanical equipment and includes demolition of buildings, construction of new buildings, laying of pipelines, sewers, and cables, and construction of new roadways and railways. Some noise is impulsive in character, such as caused by pile driving. Other noise is more continuous in nature from sources such as compressors and heavy earth-moving equipment. Noise levels on building sites can be predicted from knowledge of the sound power output of the different items of machinery. Chapter 129 explains how predictions of the noise at different locations near a building site can be made. Normally the contributions from the different sources are added on an energy basis. In some countries the predicted or measured sound pressure level from all the sources is compared with the ambient noise level when none of the sources is acting. There are few standards or test codes for the prediction and control of noise from building sites. In 2006, the only such test codes were those in Germany and the United Kingdom. These test codes provide tools for the calculation of the daytime and nighttime rating levels. These are then compared to standard ambient-noise values for decisions on the acceptability of the building site noise. Transient noise peaks on the building site can also be considered in these assessments.

Local authorities sometimes are tolerant of intense noise on a building site in order to speed up construction for economic or political purposes or to limit disruptions to road and rail traffic and the operations of public utilities. If the A-weighted sound pressure levels caused by the sources are no more than 5 to 10 dB greater than the ambient levels, they may be allowed by some authorities. But levels that are greater than 10 dB above the ambient are normally determined to be excessive and require regulation and/or control.

Using city or national ordinances, some local authorities impose penalties for impulsive noise and/or noise containing prominent pure-tone components. Other local authorities restrict noise in certain city zones and others only during nighttime. In some cases noise control programs are initiated when repeated and/or frequent complaints are received. If noise control measures are found to be necessary, these should start with the noisiest sources and incorporate the normal source–path–receiver concepts as explained in Chapters 54 and 129. As discussed in Chapters 126 and 129, the European Union (EU) Directive 2000/14/EC requires construction equipment machinery used on building sites to be subject to noise labeling. This EU directive requires the manufacturer to

state the guaranteed sound power level in the operating instructions and on the machine itself with a label. The determination of the sound power level is usually carried out in accordance with ISO 3744. Some of these construction machines are subject to sound power level limits.

13 COMMUNITY NOISE ORDINANCES

The major sources of noise in the community are caused by surface transportation, aircraft/airports, industry, and construction.⁷⁰⁻⁷⁸ As discussed in Chapter 130, the main contribution to community noise, in most countries, is caused by road and rail traffic. The annoyance caused by noise depends upon the level, duration, time of day, frequency content, and other factors. Road traffic noise depends upon the road surface, road inclination, traffic density and mix, and speed of automobiles and light and heavy trucks. Railroad noise depends upon vehicle speed, load, wheel and rail roughness, and other factors. Some of these sources can be controlled locally by regulation, such as with speed limits. Some factors are outside local control.

Community noise regulations and noise ordinances are of two main types: qualitative and quantitative. Qualitative types of noise ordinances prohibit excessive noise during certain hours of the day or night and/or prohibit some noisy activities during certain hours and in certain defined noise zones. The difficulty with such ordinances is that they are vague in nature and difficult to enforce. Quantitative noise ordinances, however, restrict noise generated and/or received. The levels allowed at the boundary where they are produced or the boundary where they are received are normally given as A-weighted sound pressure levels. These quantitative ordinances need trained staff for enforcement who can use calibrated measurement instruments to determine the sound pressure levels accurately. Since noise levels fluctuate in the community and vary during day, evening, and night periods, average levels are often used such as the equivalent sound pressure level. The A-weighted equivalent sound pressure level came into use in the United States in the 1970s, and recommendations have been published by the World Health Organization (WHO) for day and nighttime to protect people from becoming moderately or seriously annoyed. In the United States the day-night average sound pressure level is also widely used. This is calculated from the equivalent day time sound pressure level and the equivalent nighttime sound pressure level to which a 10-dB penalty is applied to sound occurring between 10 p.m. and 7 a.m.. In Europe the day-evening-night sound pressure level is now increasingly used. This is similar to the day-night average sound pressure level but is calculated from three periods with a 5-dB penalty applied during evening hours and a 10-dB penalty applied during nighttime.

Some noise ordinances specify different noise zones that are defined for the activities performed in the zones. Zones can be specified for heavy industry, light industry, residential, school, hospital, and other uses. Normally different noise zones are created with steps of 5 dB from noisiest to quietest zone with restrictions

on the maximum noise permitted in each zone. For instance, some activities such as construction may be prohibited in some zones. Obviously, enforcement is essential if the ordinance is to have any use at all. Fines and other financial penalties can be used for enforcement. In the United States, the Office of Noise Abatement and Control set limits for noise output of some sources such as heavy trucks and compressors on building sites and was active in producing a model community noise ordinance standard. Since 1980 centralized planning by the EPA Office of Noise Abatement and Control has largely been disbanded and taken up by different government agencies and local, citywide, or state authorities. In Europe, a different situation exists. European directives in recent years have required strategic noise maps to be created for major transportation facilities such as airports and railway stations and for large cities. Action plans are required to manage noise problems and recommend noise reduction if necessary. The goal is to harmonize noise criteria and noise zoning and limits among the different European member states. The experience in other countries such as Australia, Canada, China, and Japan is described in detail in Chapter 130. Further work and discussion on community noise evaluation and ordinances and regulations continues.⁷⁰⁻⁷⁸

CHAPTER 120

EXTERIOR NOISE OF VEHICLES – TRAFFIC NOISE PREDICTION AND CONTROL

Paul R. Donovan
Illingworth and Rodkin
Petaluma, California

Richard Schumacher
R. S. Beratung LLC
Fenton, Michigan

1 INTRODUCTION

Noise from motor vehicles is arguably the most pervasive of all environmental noises.^{1,2} Although the noise levels of individual passenger cars, trucks, buses, and motorcycles are relatively low compared to airplanes and trains at equivalent distances, their shear numbers and close proximity to sensitive receptors more than offset their lower source levels. For this reason, considerable attention is given to controlling exterior motor vehicle noise at the source, abating noise from traffic flows, and planning appropriate land uses in the vicinity of highways. In this chapter, noise emissions from motor vehicles are examined individually and collectively in traffic flows. Because of their greater volumes, the noise from passenger cars and trucks tend to dominate traffic noise. Further, because trucks have in-service source levels that can be on the order of 10 dB higher than cars, the level of traffic noise is also strongly influenced by the mix of cars and trucks. To address the noise of individual vehicles, regulations are in place in most countries to limit the noise production by vehicle category. To address the noise from traffic flows, measurement protocols are available, as are various traffic noise models. These models typically not only predict traffic levels but are also used to assess different noise abatement strategies.

2 NOISE OF INDIVIDUAL VEHICLES

In the broadest sense, the sources of the exterior motor vehicle noise are considered in three categories: power train, tire–pavement, and aerodynamic noise. Power train noise is taken here to include all sources associated with vehicle propulsion, including noise from the engine, induction system, engine accessories, transmission and gears, cooling fan, and so forth. Also included in power train noise is exhaust outlet noise; however, this is often considered separately. Of the three categories, power train and aerodynamic noise are solely properties of the vehicle while tire–pavement noise is both a function of the vehicle (tires) and the pavement on which it operates. The contribution of these sources to the total exterior noise produced by a vehicle depends on the general type of motor vehicle, its operating condition, and its environment. Motor vehicles are typically

grouped as light vehicles (passenger cars, pickup trucks, sport utility vehicles, and passenger size vans), medium trucks, heavy trucks, buses, and motorcycles. In the United States, light vehicle are defined as being less than a gross vehicle weight (GVW) of 4500 kg, medium trucks have single-drive axles with a GVW of 4500 to 12,000 kg, and heavy trucks have multiple-drive axles with a GVW typically over 12,000 kg.³ The operating conditions typically considered include acceleration, cruise, upgrade, deceleration, and idle. For modeling and assessing traffic noise, idle and deceleration are generally not considered with the possible exception of engine compression breaking of heavy trucks. The dependency of motor vehicle noise sources on environment is primarily due to pavement type; however, temperature is also generally acknowledged to have an effect on both power train and tire–pavement noise on the order of 1 dB/10°C.^{4–6}

Each of the three noise source categories has its own typical dependency on vehicle operating parameters. Powertrain noise is dictated primarily by engine speed [revolutions/minute (rpm)] and load. Power train noise typically increases proportionally to 30 times log (rpm) and increases by about 2 to 3 dB for partial versus full throttle.⁷ Power train noise does not show a constant relationship to vehicle speed, as the ratio between these is a function of gearing and gear selection. Tire–pavement noise is primarily a function of vehicle speed, V . Generally, tire–pavement noise increases proportionally to 30 to 35 times log(V), although a very wide range in the multiplier has been reported in the literature.⁸ Tire–pavement noise is also known to depend on applied torque during acceleration. This effect can increase the noise produced by 0 to 8 dB, depending on the tire design and construction and on the applied torque.⁹ Aerodynamic noise is also dictated by vehicle speed, typically proportionally to 60 times log(V). An example of how these sources combine based on these relationships and actual data^{9,10} is shown in Fig. 1 for a composite of light vehicles operating under cruise, road-load conditions.

Two types of the test procedures are used for the measurement of individual vehicles. These are controlled passby tests, such as Society of Automotive Engineers

Figure 1 Typical contribution of passenger car noise sources under cruise conditions as a function of speed.

(SAE) J986¹¹ and International Organization for Standardization (ISO) 362,¹² and statistical passby tests, such as ISO 11819-1,¹³ and those specified by the U.S. Federal Highway Administration (FHWA).¹⁴ In controlled passby tests, a single test vehicle is driven by microphone(s) at a distance of 7.5 m and/or 15 m set at a height of 1.2 or 1.5 m (5 ft). The maximum A-weighted sound pressure level measured using a $\frac{1}{8}$ -s (fast) exponential averaging time is reported. Operation of the vehicle is closely controlled, and often the tests are done on closed test tracks. These tests are typically used to determine differences between vehicles or tires with other variables held constant. In field situations, controlled passby tests are also used to isolate pavement effects for a vehicle(s) with specific test tires. Statistical passby tests are made of randomly occurring vehicles operating on public roadways. These tests are typically used to determine the range and average of noise levels within vehicle categories at one or more sites. Microphone placement and data measurement and reporting are the same as controlled passbys. Because vehicle speed is not controlled, the passby levels must be examined as a function of speed. The speed of each vehicle must be determined externally. Differences in the noise level–speed relationship are then used to compare site-specific issues such as pavement type or to compare noise from vehicle categories. Because of the variability of the noise from individual vehicles and the fact that vehicle speed is not controlled, statistical passby methods require many data points to achieve stable results.

Much has been done to characterize noise produced by various vehicle types in Europe and the United States using statistical passby methods. Under cruise conditions, these data typically show a large range in

noise level for individual vehicles at any given speed and within a given vehicle category. Ranges for individual vehicles of 10 dB in each category are common across multiple sites in the speed range from 50 to 115 km/h. By segregating the sites by pavement type, this range is reduced by a few decibels, however, even for a single site, the typical range in individual vehicle noise level is typically 4 to 6 dB. Most of this variation can be accounted for by tire noise, which ranges by about 5 dB within a vehicle category. However, some variation is also due to higher noise levels generated by modified vehicles or ones with faulty exhaust systems. An example of statistical passby data for light vehicles taken at a single site only is shown in Fig. 2.

The largest and most recent database of statistical passby levels in the United States was reported by the U.S. Department of Transportation in 1995.³ This data set consists of over 6000 individual passby events collected over 40 sites in different areas of the United States. Regression lines corresponding to the mean energy emission of five categories of vehicles are shown in Fig. 3 normalized to a distance of 15 m and averaged over all pavement types.

The data were also analyzed by pavement groupings of Portland cement concrete (PCC), dense graded asphalt concrete (DGAC), and open graded asphalt concrete (OGAC). The greatest effect of pavement was seen for automobiles and light trucks at speeds above 50 km/h where the averaged difference between PCC and OGAC reached about 4.5 dB. For medium and heavy trucks, this difference was about 2.5 dB above 65 to 80 km/h. Data from European studies display similar effects of vehicle and pavement type.¹⁵ For

Figure 2 Statistical passby test results for automobiles measured at 15 m from I-895.¹

Figure 3 Emission level comparison of various vehicle categories in the United States at a measurement distance of 15 m.¹

comparison, the average of mean energy emission levels taken from three European studies¹⁵⁻¹⁷ have been energy averaged and compared to the U.S. levels in Fig. 4 as normalized to a distance of 7.5 m.

3 REGULATION OF MOTOR VEHICLE NOISE

Regulatory test procedures are an adaptation of the technical standard developed by an engineering body specializing in the measurement of product characteristics. The ISO dominates the regulatory procedures in European countries. In addition, other countries have procedures identical to the European countries or refer directly to a specific European regulation. In some

cases, the ISO procedures have been modified by the implementing country leading to a variety of similar but often different regulatory procedures.

The United States and Canada followed the development of procedures by the SAE. California, the first state to adopt a vehicle noise certification procedure, used the SAE J986 and SAE J366¹⁸ for cars and trucks, respectively. The operating modes in ISO and SAE are similar, using acceleration from a stabilized approach speed around 50 km/h up to a higher speed but limit the engine speed to being equal to or less than the rated power engine speed. The SAE-based procedures

Figure 4 Comparison of vehicle emission levels from the United States and average of European studies normalized to a measurement distance of 7.5 m. ^{1,10–12}

required approximately twice the physical measurement area of the comparable ISO tests area with the measurement microphone 15 m from the driving lane for SAE versus 7.5 m for the ISO. The regulatory limits under these test procedures are given in Table 1 as of 2003. Static tests intended to monitor changes in the exhaust system performance or intentional modification are also in place in some jurisdictions. Both static and moving tests can identify a defective exhaust component, however, the no-load static tests are not otherwise correlated to passby tests.

The UN member countries have developed the 1998 Global Agreement, which modifies some of the mandatory requirements of 1958. Consequently, United Nations (UN) influence on noise procedures

and limits now includes most of the countries included in the 1958 agreement and also the United States, South Africa, China, and Russia as well as the major non-Western Europe areas that effectively make it a true global regulation. The consequences of this action are not yet known in many countries including the United States.

There has been some concern expressed about the effectiveness of new vehicle noise regulations in reducing noise levels in the community. The European Union 1995 Green Paper concluded the two decades of reductions of limits have not provided the desired improvement in the community exposure.¹⁹ The reasons for the limited effectiveness were later identified to include slow exchange rate of older, noisier vehicles

to new, quiet ones; a trend toward bigger, more powerful trucks and light vehicles; lack of in-use controls; the underlying levels of tire–pavement noise; and a lack of a test procedure that represents actual vehicle operation.¹ Studies have shown the driving mode in the community is significantly less severe than the regulatory test. As a result, product design modifications are introduced for engine speeds higher than in use operation. In addition, the emphasis on power train noise conceals the contribution of tires that occurs even at the lower vehicle speeds near 30 km/h. Consequently, the ISO has embarked on developing a more representative urban rating that includes a power-train-dominated full-throttle mode and a tire-dominated constant speed. These are combined to yield a level that more closely represents the noise impact of urban traffic. The European regulations have also added a high-speed tire noise rolling test that addresses the highway noise problem. But the initial levels and step reductions along with the rate of vehicle exchange will delay any meaningful improvement for over a decade.

The U.S. consumer interest in vehicle noise regulation has been very limited. Early regulation reduced the initially higher exhaust levels, which was the public perception of vehicle noise problems. Although there is no conclusive noise data, trends in the United States support the notion of generally increasing traffic levels. The tire–pavement noise levels on U.S. freeways have led to residential complaints that have resulted in freeway noise barriers and the advent of major research on quiet highway surfaces. In 1968, when the first noise regulation was adopted in California, the average family of 3.4 people²⁰ owned one vehicle. Today, the average family of 2.7 people has two vehicles plus one recreational or off-road vehicle suggesting increased volumes of traffic.²⁰ In addition the predominance of sport-utility-styled vehicles has increased the tire noise component of the vehicle noise because of the more aggressive tires, which are intended for multiple season and recreational driving. Finally, the speed limits on the interstate system and regional highways are higher than 20 years ago. To address these trends, future test procedures must be developed to deal with the annoyance of the urban community, reflecting the manner in which vehicles are actually operated. Test procedures must rate the tire noise source as it impacts the urban and rural resident under a range of operating speeds from 60 km/h through 100 km/h. In addition, regulations must restrict the modification of vehicles to ensure that in-service vehicles continue to meet the design standard.

The international procedure groups must continue to be active in the development of tests that address the increasing range of products from the traditional internal combustion cars through the innovative electric vehicle with a variety of power sources. With the possible exception of motorcycles³ all vehicles, regardless of the power source, have a significant tire component that becomes a more significant part of the total vehicle as the power train levels are reduced.

4 VEHICLE NOISE IN TRAFFIC FLOWS

Because of the levels produced, traffic noise from freeways and multilane highways tends to be a primary source of concern for community noise. The basic parameters governing the noise generation from highways are average vehicle speed, traffic volume, mix of light vehicles and trucks, and pavement type. Above 80 km/h, the composite noise from a traffic flow of cars and trucks increases at about $35 \log(V)$ (Fig. 3). At these speeds, since trucks are about 5 to 9 dB louder than light vehicles (Fig. 4), the traffic noise depends on the percentage of medium and heavy trucks as well as the total number of vehicles. Within each vehicle category, the noise level increases by 3 dB with each doubling of volume. The effects of pavement depend not only on the type of pavement present but also on the traffic mix. However, even with relatively high truck volumes, the pavement can cause differences in highway traffic noise of 6 dB or more.

The temporal nature of noise from highways also depends on traffic volume and mix as well as distance to the roadway. For higher volumes and/or further distances from the roadway, the short-term noise levels display little variation. At higher volumes, multiple individual vehicles determine the resultant noise so that there is little variation in noise from moment to moment. Similarly, at larger distances, more individual vehicles contribute to the noise because the distance to each vehicle is similar over a longer length of roadway. For lower traffic volumes and/or close distances, temporal variations of 30 to 40 dB or more can occur depending on background noise, the noise produced by an individual vehicle, and the distance away. An illustration of several measured temporal variations are given in Fig. 5 for different traffic volumes and distances from urban area freeways.

Reflecting the difference in day and nighttime traffic volumes, noise from major arterial roadways and highways often displays a consistent diurnal pattern for levels measured on an hourly basis.²¹ Under this pattern, the lowest hourly levels characteristically occur in the early morning (1:00 to 3:00 a.m.) when traffic volumes are lower, rise rapidly to about 6:00 or 7:00 a.m., remain constant to after 6:00 p.m., and then fall off toward the early morning minimum. This pattern as measured for 28 different roadways is illustrated in Fig. 6. In congested areas, the hour of highest noise level and the hour of peak traffic volume are not necessarily the same due to reduced speeds at highest volumes.

For arterial roadways, the freeway diurnal noise pattern is also often present. In addition to the short-term temporal variations noted for highways, the presence of traffic control devices can also influence the temporal variation of noise from arterial roadways. Even away from intersections, traffic lights can create “platooning,” where groups of vehicles pass by a location followed by long periods of no vehicles. At controlled intersections, the noise of the traffic is different both in terms of its temporal variation and character.^{22,23} At traffic lights, there will be periods of time when vehicles are idling, producing relatively

Figure 5 Variation of overall A-weighted sound pressure level (slow response) over 15 min for heavy traffic and light traffic as measured at 15 m.

Figure 6 Typical diurnal pattern of noise levels from roadway.¹⁷

Figure 7 Vehicle noise emission levels for nonaccelerating and interrupted flow/grade operating conditions.¹

low noise levels, followed by vehicles accelerating from rest and periods of cruise conditions. Unlike cruise where the noise emission is heavily influenced by tire–pavement noise, during acceleration, the noise emission is initially influenced by power train noise. Especially for trucks, the character of this sound is distinctive as the noise is very much a function of engine rpm, and noise will have a “saw-tooth” pattern as the truck uses several gears to gain speed.^{24,25} Because of gearing differences and the prevalence of automotive transmissions, this characteristic is not as pronounced in light vehicles. However, the difference between low-speed cruise and acceleration is much greater for light vehicles than for trucks (Fig. 7).

Traffic noise is typically characterized using the equivalent sound pressure level (L_{eq}) metric instead of maximum passby level. The time period over which the L_{eq} is determined can vary with the traffic density or temporal variation of the noise, however, a minimum of 2 min is specified for “steady” traffic noise and up to 30 min where the anticipated range in sound pressure level fluctuation is greater than 30 dB.¹⁴ Three to six repetitions over the selected time period are also recommended. The details of measurement depend on the intent of the measurement. In cases where it is desired to assess the environmental noise impact at a specific location, measurements in hourly intervals over a 24-h period are typically made so that the day–night sound pressure level (L_{dn}) or the community noise equivalent level (CNEL) values can be determined. Measurement locations are typically near the location for which the impact is to be assessed. Measurement of traffic speed and volume are not necessarily required and the measurements are often unattended. When the intent of the measurement is

to compare before and after levels when a roadway change is planned, or to compare the measurements to traffic model results, or to compare one site to another, additional documentation is required. In these cases, the noise measurements are typically shorter, lasting several hours, and are usually attended so that unusual occurrences and noises can be identified and removed. The measurement of traffic volume and average vehicle speed by category is also required. In addition, documentation of the site geometry and conditions, ground type and cover, and meteorological conditions are also needed. For before and after measurements, microphones are placed at standard locations or near sensitive receptors; however, a reference microphone 30 m or less from the center of the nearest travel lane is desirable. For comparison between sites or to traffic models, measurement sites should be flat and free from extraneous reflecting surfaces within at least 30 m of the traffic and microphone locations. One microphone is placed 15 m from the center of the near lane of vehicle travel at a height of 1.5 m above the plane of vehicle travel. Additional microphones at 7.5 m and 30 m are often used, as are microphones at greater heights than 1.5 m. Wind speed should not exceed 19 km/h (12 mph) during the measurements.¹⁴ With these criteria, research-grade measurements are not possible in many situations.

5 PROPAGATION OF TRAFFIC NOISE

The underlying nature of sound propagation away from individual vehicles is that of a *point source* over a reflecting plane. This leads to a general behavior of spherical divergence or a 6-dB reduction in sound pressure level with each doubling of distance (DD) or as given by $20 \log(r/r_o)$. As a result, maximum

passby levels of individual vehicles falloff at a rate of about 6 dB/DD for propagation over acoustically hard, relatively flat ground for distances of 30 m or less. For traffic flows, the individual point sources are spread out into a continuous line of sources. In this case, the general behavior is that of cylindrical divergence or a 3-dB reduction in level with each doubling of distance [$10 \log(r/r_0)$]. In urban settings, for propagation down a side street away from a traffic line source, the sound also decreases at about 3 dB/DD after about an initial 2-dB amplification due to reflections from the building surfaces.²⁴ For time-averaged metrics of vehicle passbys, such as the single event level (SEL), the averaged level also decreases at 3 dB/DD for open areas.

A number of different phenomena often occur to complicate the ideal propagation models discussed above. At distances close to the line of vehicle passby, constructive and destructive interference patterns occur, modifying the spectrum of the received sound and its overall A-weighted level. This interference is a function of the path length difference between the direct and reflected sound waves propagating from the vehicle and the impedance of the intervening ground. At farther distances, a number of other factors influence the sound propagation from vehicles and traffic flows. In open areas, these include temperature and wind gradients, propagation over acoustically "soft" ground, and atmospheric air absorption.²⁶ The net effect of these factors is to generally provide more sound attenuation than that predicted by the ideal spreading laws. As a result, applying the theoretical attenuation of 3 dB/DD for traffic flows or 6 dB/DD for individual vehicles tends to predict higher levels than those that actually occur. Of these factors, only attenuation by atmospheric absorption is generally considered not a source of noise level variation, although it is a function of relative humidity. Wind tends to be the most volatile in terms of effect on propagation due to its variation in both speed and direction. At distances as close as 30 m from a freeway, differences in noise due to wind changes can be as great as 5 to 6 dB even for relatively light wind conditions. For improved consistency in data, it is preferred to measure vehicle and traffic noise under conditions of virtually no wind or when the wind is in a cross direction between the roadway and measurement location or when the wind is in the direction from the roadway to the microphone (downwind). Upwind conditions should be avoided due to the potential for substantial excess attenuation in the resultant shadow zones.

In situations where other forms of excess attenuation exist, wind and temperature effects can reduce the effectiveness of the attenuation and result in higher levels than those normally occurring. When barriers, buildings, or topography provide the shielding between the traffic source and receiver, the downward bending of the sound rays with downwind propagation and temperature inversions can reduce the shielding provided by these obstacles. They can also nullify the effects of excess ground attenuation. As a result, for residences exposed to traffic noise, the received levels

can noticeably increase over what normally occurs in cases where excess attenuation is commonly present due to barriers and obstacles, ground attenuation, or prevailing wind conditions.

6 MODELING OF TRAFFIC NOISE

Modeling of traffic noise has several uses, including estimating current noise exposure along roadways, assessing the effect of roadway changes, and predicting the performance of noise abatement options. The basic elements of traffic noise modeling are the traffic source levels and the propagation or attenuation of sound between the traffic and the receiver. Typical source-related inputs to traffic noise models are the speed and volume of vehicle types, operating mode of the vehicles, and the length of roadway with line of sight to the receiver location. Propagation-related inputs include the acoustic characteristics of the ground, the number of lanes of travel, site geometry and topography, and the type and geometry of any barriers or buildings present. Most models also consider the type of pavement at the site in regard to tire-pavement noise generation, the prevailing wind and temperature conditions,²⁷ and interrupted traffic flows.²² There are a number of resources that can be consulted for additional, detailed information about traffic noise prediction methods.^{26,28-30}

Embedded in traffic noise prediction routines are some assumptions about the vertical distribution of source strength on the vehicles for the operating mode under consideration. Knowledge of source height is critical for predicting propagation effects and the effectiveness of the barriers. Under cruise conditions for properly maintained cars and trucks, tire-pavement noise typically begins to dominate power train noise at speeds above about 40 km/h.²⁵ For trucks, the speed is found to be more in the range of 50 to 60 km/h. At any speed in which tire-pavement noise dominates, the source is known to be very close to the ground, within about 100 mm.⁸ At lower speeds, the distribution is skewed more to power train sources. For light vehicles, noise to the side of the vehicle comes from the underbody area and wheelwell areas near the engine compartment and from the exhaust outlet. These source regions are also relatively close to the ground, typically within one metre of the ground. For trucks, the engine compartments are higher, 1 to 2 m above the ground, and exhaust outlets may be as high as 4 m. Although there has been work completed worldwide on this subject,^{16,31} the data are limited. As a result, traffic models often rely on partial data and/or assumed source heights.

Worldwide, there are many traffic noise models available. Many general sound-mapping software codes have some traffic noise prediction element. Also, many countries have their own accepted model for predicting traffic noise. In the United States, the new Federal Highway Administration (FHWA) Traffic Noise Model (TNM) is replacing the older STAMINA2.1. This new model features improved sound propagation prediction, particularly for barrier insertion loss and propagation over acoustically soft ground. Unlike the

older model, TNM uses one-third octave band levels in its calculations of sound propagation.³² TNM has undergone and continues to undergo extensive validation. When a reference microphone position is used, the propagation algorithms typically provide superior results compared to older models.³³ Compared to STAMINA, TNM has been found to predict greater insertion loss by 1 to 3 dB.^{33,34} Initial validation work by the U.S. Department of Transportation DOT indicates very good agreement between calibrated field measurements and TNM results with an average difference of 0.5 dB in open areas when strong winds were not present.³⁵ Although TNM has the provision for including the effects of pavement type, use of this feature is not currently allowed. As a result, on an absolute basis, TNM can overpredict traffic noise levels by as much as 5 dB in cases where the pavement is quieter than the average pavement assumed in the model.³⁶ To improve the absolute performance of TNM and other models, it is recommended to reference the model results to measurements of existing traffic noise representative of the site made at locations within 30 m (100 ft) of the roadway.³⁵

7 ABATEMENT OF TRAFFIC NOISE

Abatement of traffic noise is driven by two distinct criteria. These are basically proactive and reactive. Proactively, for new highways or major alternations, such as adding lanes to an existing roadway, noise levels are predicted using traffic noise models. These levels are then compared to criteria that trigger the need for noise abatement to be considered. These criteria vary by country and jurisdiction. Within the European Union, 55 L_{dn} is considered the goal for exterior noise levels, while 65 L_{dn} is considered the limit of acceptable noise level.¹⁹ Each country is then expected to develop plans to reduce the level down to the 55 L_{dn} goal. In the United States, the FHWA identifies noise impact and need to consider noise abatement when the predicted levels from new highways or major alternations approach 67 dB for highest hourly L_{eq} level for noise-sensitive land uses.³⁷ States refine this criterion and commonly use hourly L_{eq} values ranging from 64 dB up to 67 dB as the threshold for considering noise abatement. At the local level, lower thresholds, such as 65 L_{dn} , are common. These mixed metrics, maximum hour L_{eq} and L_{dn} , require some reconciliation in order to compare the various criteria. Using the data of Fig. 6, the highest hour L_{eq} values of 67 dB typically equate to an L_{dn} of about 70 dB, while an upper limit of L_{dn} of 65 then translates to a highest hour L_{eq} of 62 dB. At an L_{dn} of 70 dB, slightly more than 20% of the people exposed to the traffic noise would be expected to be highly annoyed (see Chapter 34). For existing highways, similar or higher criteria are often used to identify the need for noise abatement. In these cases, negative public reaction to the traffic noise can drive noise abatement even though the levels are at or below the criteria. Also, “minor” alternations to the pavement surface such as transverse tining of PCC can initiate

the need for abatement due to increased noise level and changes in noise character.^{38,39}

Abatement of traffic noise can be considered using the traditional source–path–receiver analysis. In regard to the source, new vehicle noise emission standards are applicable as discussed previously. In-use noise levels, however, can be significantly higher due to poor maintenance or purposeful alternation. Although traffic noise levels could be significantly lowered by eliminating such vehicles from the traffic flow (refer to Fig. 2), in-use regulation and enforcement is not commonly done. Based on vehicle speed versus noise relationships (Fig. 3), traffic noise can also be reduced by lowering vehicle speed limits. Noisier vehicles, such as heavy trucks, can also be restricted on a roadway to reduce traffic noise levels. Quieter pavement surfaces are commonly used in Europe and Asia as a method of controlling noise at the source. Open graded (porous) and/or rubberized asphalt is beginning to be used in the United States for traffic noise abatement. Initially, such pavements have demonstrated the ability to reduce traffic noise up to 5 dB or more on highways and local roadways.^{36,40}

In regard to the path, noise barriers are commonly used in many countries to shield sensitive receptors from traffic. In the United States, all but six states have constructed noise barriers along their highways. Although strictly voluntary, 22 of these states have constructed barriers for the sole purpose of abating existing noise levels.⁴¹ Field performance of highway noise barriers typically provides a reduction in noise level in the range of 5 dB to 12 dB depending on the height of the barrier, the distance of the receptor location away from the barrier, and topography and acoustic characteristics of the site. Typically, noise reduction goals are established within the transportation agencies and if the stated goal is not feasible, the noise abatement project is not done. These goals commonly range from 5 to 10 dB. Noise barriers are not limited to major highways. Barriers are used for traffic noise abatement at the local level both by governmental bodies and developers when the levels along arterial streets warrant abatement. Most traffic noise models provide some algorithm for predicting barrier performance, which is used to specify barrier geometry and to predict performance. While other path-related traffic noise abatement methods include highway realignment, and acquiring land for buffer zones along the highway, these are seldom used.

In cases where the impact is severe and source–path abatement is not feasible, receiver-based abatement is considered. In this situation, air conditioning may be added to an existing building or house to reduce the need for open windows. Acoustically weaker elements of the building facade such as windows, doors, and vents may be replaced with units providing increased noise reduction. Finally, enhancement of the wall construction itself may be considered. Although not strictly abatement, noise levels experienced by sensitive receptors can be avoided through land-use planning and development. This is often done as a two-tier process where exterior noise criteria are applied as

the first level. If these cannot be met, development may still be allowed if it is demonstrated that interior criteria can be met through proper building sound insulation. These criteria are set on the state and local level.

In assessing traffic noise abatement methods to a specific application, a number of trade-off issues are involved. The use of barriers has been the long-standing method of choice. However, in some situations, barriers are not feasible because of site constraints and/or inability to produce a 5- to 10-dB reduction given the site geometry. Also, barriers may not be acceptable to the residents along a roadway due to blocking desired views and other aesthetic reasons. Use of barriers can also be restricted for safety, line-of-sight concerns. Abatement through the application of quieter pavement surface overlays has become an increasingly popular alternative. However, the effectiveness of quieter pavement surfaces depends on their improvement in noise performance relative to the original pavement and their continued noise performance over their life cycle. Although quieter pavement surfaces have been found to be cost effective in some countries and applications,⁴² they are currently not eligible for federal funding or assistance in the United States as a noise abatement method.

CHAPTER 121

RAIL SYSTEM ENVIRONMENTAL NOISE PREDICTION, ASSESSMENT, AND CONTROL

Brian Hemsworth
Noise Consultant
Derby, United Kingdom

1 INTRODUCTION

The main purpose of any environmental noise prediction scheme is to determine whether the noise levels from the source in question exceed legislative limits (if they exist) or project-determined noise assessment criteria. This means that the noise prediction scheme is used to predict noise levels in terms of a noise descriptor that correlates with annoyance.

For railways this is the prediction of the equivalent sound pressure level (L_{eq}), and there is a growing tendency for the simple 24-h L_{eq} noise level to be replaced by metrics that penalize night or evening/night traffic. The separation of the 24-h period into separate or aggregated time periods affects the detail of the operational information needed for accurate prediction but does not affect the basic prediction process.

It is more important to understand the principles on which prediction models can be developed than to attempt to provide prescriptive data for universal use in prediction models. These principles are appropriate to any surface rail system irrespective of the type of rolling stock used or the track designs. It is the role of the user to input the specific source levels and attenuation algorithms that are appropriate to the specific case under investigation.

2 PREDICTION PROCESS

A number of alternative L_{eq} -based criteria are used worldwide and are discussed in Chapters 25 and 34. For a series of individual events (such as train passages) L_{eq} can be derived from the following equation*:

$$L_{eq} = 10 \log_{10} \left[\sum_{i=1}^n 10^{SEL_i/10} \right] - 10 \log_{10} T \quad (1)$$

where SEL_i = SEL for the i th train passby
 T = assessment time period (in seconds)
 n = number of train passbys in period T

*A number of prediction schemes do not use SEL as the basic energy descriptor since SEL will invariably have a higher numerical value than the maximum A-weighted sound pressure level of the train passby and may be confusing to the general public. Alternative options such as L_{eq}/h are used¹ with the consequent change in T in Eq. (1), e.g., for 24-h L_{eq} from SEL, $T = 86,400$, for 24-h L_{eq} from hourly L_{eq} , $T = 24$.

For a particular receiver position a train service can be considered as a number of repeated noise events (N_i) and the summation equation for each train type is simplified to

$$L_{eq_i} = SEL_i + 10 \log_{10} N_i - 10 \log_{10} T \quad (2)$$

where the suffix i refers to types of trains with identical noise characteristics. Thus

$$L_{eq} = 10 \log_{10} \left[\sum_{i=1}^m 10^{L_{eq_i}/10} \right] \quad (3)$$

where m is the number of types of trains.

It is therefore necessary to be able to predict the noise level caused by a single train passby (SEL_i) from knowledge of its source characteristics and the propagation from the source to the receiver position.

Figure 1 shows a typical prediction flow diagram where the noise level (SEL in this example) is predicted for all trains on each track and summed over the relevant time period to give total L_{eq} . From a computational point of view the logic is for source noise to be summated for each track before entering a propagation loop, but this can be varied depending on whether it is important to identify which “train type” gives the highest noise level or the track which contributes most to the overall noise level.

In some prediction models the calculation process is in one-third octave or octave band levels. This does not alter the procedure described below but naturally requires more detailed information for each element of the calculation and a summation stage from frequency data into overall noise level. Each of the elements in the prediction process is summarized in the following sections.

3 SOURCE NOISE LEVELS

Three sources are considered:

- Rolling noise
- Power unit noise
- Aerodynamic noise

The first step in the process is to identify the free-field source related noise levels, before taking account of propagation effects. This is normally defined as a

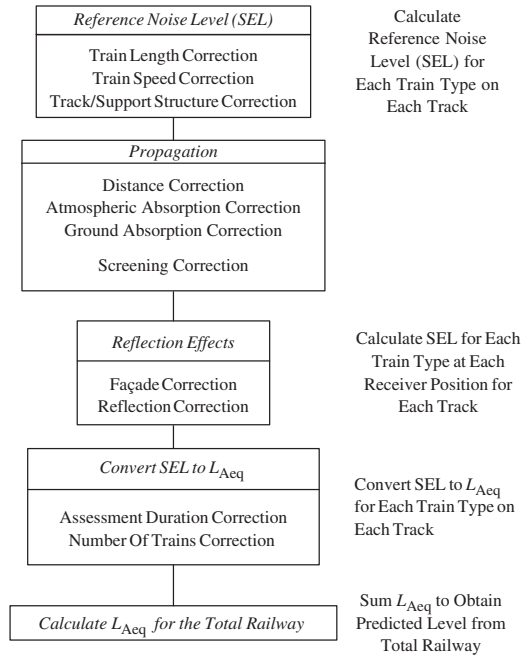

Figure 1 Railway noise prediction flow diagram.

noise level at a close distance from the track with the ground on the same level as the track. Different models use different reference distances, but the choice is not critical and the majority use a distance of 25 m relative to the track. This allows empirical data to be obtained for trains at all speeds without the danger of aerodynamic effects on microphones from high-speed trains.

3.1 Rolling Noise

Rolling noise is always present and must be included in any prediction model. Chapter 93 describes the background to rolling noise and identifies the major generation parameters as train speed and wheel–rail roughness.

Figure 2 shows the results of regression analysis of single-vehicle SEL [total SEL – $10 \log N$ (where N = number of vehicles in train)] as a function of train speed for a number of passenger trains on continuously welded rail. This clearly demonstrates the difference in noise level between vehicles with cast-iron tread brakes and disk brakes.

The reason for this change in noise level is due to differences in wheel surface roughness produced by the different braking systems (see Chapter 93). The use of cast-iron tread brakes is reducing and has almost been completely replaced on passenger vehicles by disk brakes. Many freight vehicles in Europe are still braked using cast-iron tread brake blocks, but current initiatives involve replacement of these with tread brakes using brake blocks of composite materials. There is evidence to show reduced noise levels from

Figure 2 Example result of regression analysis for passenger vehicles.

these vehicles (again because of reduced wheel surface roughness levels) but comprehensive data on wheel roughness and noise levels are lacking, and it is currently believed that the noise characteristics of composition block tread braked trains are the same as disk braked trains. This needs to be confirmed, and it is therefore necessary that for new train designs, empirical data, similar to that shown in Fig. 2, is obtained for input to a prediction scheme to provide further information for “Train type” in Eq. 2.

Following normal convention, a speed function takes the form of

$$L_{Amax} = k \log(V) + C \quad (4)$$

where V is train speed and C is a constant; and it is commonly taken that $k = 30$ can be used without serious loss of accuracy. This value will certainly be used in situations where data were obtained with insufficient speed range to provide a reliable regression analysis.

For a maximum passby noise speed function of $30 \log(V)$, it follows that noise energy (SEL) will have a speed function of $20 \log(V)$, and most prediction models include a $20 \log(V)$ speed function for rolling noise SEL as is shown in Fig. 2. The usual modeling of rolling noise is to assume the train to be a line of incoherent dipoles. From this it can be assumed that for a receiver located approximately 25 m from the track, the maximum sound pressure level is independent of train length (for trains longer than say 50 m) since for these close distances the contribution from sources at the extremities of the line is negligible.

The length of the line source is, however, important in determining SEL since for a given train speed, train length will affect the duration of the noise signal. The correction term for train length is

$$10 \log(TL/TL_0) \quad (5)$$

where TL is train length and subscript 0 refers to an arbitrary reference.

It is more common to assess train length correction by the number of identical vehicles in the train since this information is likely to be a more readily available parameter. Thus it is necessary to provide an equation for SEL for a reference train length and modify this by Eq. (5) for the train in question.

Using the noise level versus speed relationships above, a doubling of speed gives a change in the A-weighted noise level L_{Amax} of 9 dB and 6 dB in the A-weighted SEL. The difference (at the same speed) in the A-weighted noise level between cast-iron tread-braked passenger vehicles and disk-braked passenger vehicles is about 10 dB in both L_{Amax} and A-weighted SEL. A train of disk-braked vehicles will therefore need to travel at approximately three times the speed of an identical train of cast-iron tread-braked vehicles to produce the same noise energy. Thus, for accurate prediction it is important to know the train speed and train type, particularly the form of braking utilized.

These reference levels are derived from measurements of the noise from train passbys. It is therefore important to define the measurement conditions that should be used. A number of standards exist, for example, Ref. 2, each with slight differences in detail. There are, however, a number of common features:

- Track to be good quality continuously welded rail, supported by concrete sleepers on ballasted track
- Free-field conditions
- Dry conditions
- Wind speed <5 m/s
- Wind direction from track to receiver

3.2 Diesel Locomotive on Power

The noise from a diesel locomotive on full power, and particularly at low speeds (see Chapters 93 and 97), needs to be treated separately from its rolling noise and is considered as an additional noise source. The maximum sound pressure level for this situation is usually independent of train speed, SEL will therefore reduce by $10 \log(V)$ as speed increases because of the reduced duration of the noise event.

For older generation diesel locomotives, the UK prediction scheme³ is based on a free-field maximum A-weighted sound pressure level of 90 dB at 25 m from the track. Using the modeling of a locomotive as a point source with cosine directivity gives the following relationship:

$$SEL = L_{Amax} + 10 \log(d/V) + 8.6 \quad (6)$$

where d is distance from track (m) and V train speed (km/h).

For the reference conditions of $d = 25$ m, this becomes

$$SEL_0 = 112.6 - 10 \log(V) \quad (7)$$

In carrying out noise predictions it is therefore necessary to identify those locations where diesel locomotives will be regularly on power. Reference 4 suggests two

common situations as (a) a train accelerating with a heavy trailing load and (b) a train traversing an uphill gradient. One useful addition to a noise prediction suite would be to link the source noise data with train performance data. This would automatically give train speed by geographic location and identify those areas where the locomotive was generally on power.

3.3 Aerodynamic Noise

Classical aerodynamic noise is generated from fluctuations in the turbulent boundary layer, from flow over sharp edges and protuberances, cavities, and the wake. For trains the main sources have been identified as the leading bogie area and the pantograph.⁵ Aerodynamic noise generation is dealt with in Chapters 9, 87, and 88.

As train speeds increase, there is the possibility that this source may become significant. The major problem, if it does occur, is that it will have a speed function approaching V^8 , which is in excess of the other sources associated with train noise. Thus once aerodynamic noise becomes a major contributory noise source in a design, any attempt to increase speed without changing that design will give rise to higher noise levels than expected.

The speed at which aerodynamic noise becomes significant depends on a number of design factors, and it is not usually an issue for train speeds below 200 km/h. In Japan it can be the most important noise source at speeds in excess of 270 km/h.⁶

Aerodynamic noise may become significant at lower speeds when lineside noise barriers are used. If the aerodynamic A-weighted noise level is within say 10 dB of the total rolling noise level, because its source will be well above rail level, the barrier will attenuate that noise less than rolling noise. Then predictions using standard barrier formulas may overestimate that barrier's effectiveness because the barrier equation is likely to have been developed in the absence of aerodynamic noise.

Aerodynamic noise can be predicted from first principles, but it is more likely that total train noise will be measured to high speeds giving relationships similar to that shown in Fig. 2 but with a change in function of speed at the higher speeds.

4 PROPAGATION OF TRAIN NOISE

It is normal for the railway to be modeled as a series of straight-line segments, and the propagation of noise reflects this modeling.* It is possible to derive an empirical relationship from measurements, but the final prediction will more than likely have to take into account the fact that some of the segments are of finite length. For this it is necessary to quantify the component parts that comprise total attenuation.

The prediction can be defined by the following equation:

$$L = L_0 - \Delta_{geo} - \Delta_{air} - \Delta_{grnd} - \Delta_{screen} + \Delta_{refl} \quad (8)$$

*A segment is defined as the length of track over which the noise source and propagation characteristics are constant. Thus determination of segment extremities will consider train speed, train numbers, and propagation features, particularly the location of barriers to free propagation.

where L = noise level at the receiver

L_0 = train specific reference noise level for actual conditions of train and track (Section 2)

Δ_{geo} = attenuation due to geometric spreading

Δ_{air} = atmospheric absorption correction

Δ_{grnd} = ground absorption correction

Δ_{screen} = attenuation such as track in cutting, lineside noise barriers or housing development

Δ_{refl} = reflection corrections, including the effect of the facade

4.1 Geometric Attenuation Δ_{geo}

The geometric decay of noise energy (SEL) from a source of constant sound power, moving on an infinite straight line at uniform speed, can be shown to be

$$\Delta_{\text{geo}} = 10 \log(d/d_0)$$

where d = receiver distance

d_0 = reference distance

and distance is measured along a line normal to the straight-line trajectory of the source.

This relationship is valid for line and point sources and is independent of source directivity. Where the movement is over a finite path length, an angle of view correction is required. This is a function of source directivity, segment length, and distance between source and receiver.

4.2 Air Attenuation Δ_{air}

Sound propagation over relatively short distances in air involves slight losses that are frequency, temperature, and humidity dependent. Since the vehicle reference noise levels will have been obtained from measurement, with air attenuation, this correction will be zero at the reference distance. A linear function is normally taken with A-weighted attenuation values ranging from 0.5 dB to 1 dB per 100 m and each prediction model will have reviewed available data to include a value for air attenuation that is consistent with the way the propagation model has been defined.

The air absorption correction is not usually applied to the engine-generated noise from a diesel locomotive on full power because of its low-frequency content.

4.3 Ground Attenuation Δ_{grnd}

Two variables, distance from the track and mean propagation path height above ground level, are taken into account with the ground generally considered as either soft (to represent flat grassland) or hard (to represent concrete or water). As the height of the propagation path above the ground increases, the absorption of the propagating wave by that ground reduces, and for a mean path height greater than about 6 m it is often assumed to be zero.

Here again the location of the assumed source needs to be defined, and for diesel power noise, with the source taken to be 4 m above the rail level, the ground is predicted to have less influence on the received noise

Figure 3 Decay of SEL with distance. (From Ref. 3.)

level. The maximum effect of the ground in Ref. 3 is taken as $3 \log(d/25)$ for a mean path height less than 1 m. This decreases linearly to zero at a mean path height of 6 m. Thus at a distance of 300 m from the railway the maximum A-weighted ground attenuation will be slightly in excess of 3 dB.

Figure 3 compares the predicted effect of combining the above attenuation terms in Ref. 3 with measured data. This figure is derived from the difference in noise level between simultaneous measurements taken at the reference distance (in this case 25 m from the track) and the quoted distance for the same train. It indicates a reasonable fit and also shows the increased variability of noise as distance from the track increases even in the situation of only accepting data for low wind speeds (<5 m/s) in the direction from track to receiver. In this example the range in the A-weighted noise level measurements at 200 m from the track is in excess of 15 dB, indicating the difficulty in comparing the results obtained from a single measurement with predictions from a model aimed at determining an average noise level.

Traditionally, noise prediction models have aimed at predicting the *average worst case*, which was taken to be the situation with the wind in the direction from the source to receiver. The European Commission's Environmental Noise Directive⁷ requires noise levels to be predicted in terms of L_{den} where the constituent parts (L_{day} , L_{evening} , and L_{night}) are the "A-weighted long term average sound pressure levels as defined in ISO 1996-2:1987, determined over all the day/evening/night periods of a year, . . . a year is a relevant year as regards the emission of sound and an average year as regards the meteorological circumstances."⁷ This implies a need for assessing local meteorological conditions over a year period and including in the propagation model the effects of different meteorological conditions.

4.4 Screening Attenuation Δ_{screen}

Obstacles to free propagation occur in the form of railways in cuttings, the shoulders of embankments, solid station platforms, purpose-built noise barriers, or building development adjacent to the track. As with most other data that is used in the prediction model, the results for screening attenuation are generally

empirical. Discussion of the principles of attenuation from barriers is presented in Chapters 58 and 122.

It is common practice when assessing the performance of noise barriers to use the higher of the predicted barrier effect and ground attenuation. This has to be recognized when deriving a performance relationship from measured data. A number of screening algorithms can be found in the literature, but it is important to remember that a barrier prediction curve is only valid for the quoted source location, and the only way of comparing prediction equations with different source positions is to carry out predictions for specific source-barrier-receiver geometries.

Barrier design is also important in determining its effectiveness. It is likely that barriers will be built as close as 3 m to the rail (safety and track maintenance limitation will restrict the use of closer barriers), and this means that the effect of a reflected wave between the side of the rail vehicle and the barrier can be an influencing factor.⁸ Barrier equations that attempt to quantify this effect are given in Ref. 3, which proposes a two-stage prediction for reflective barriers.

$$\Delta_{\text{barrier}} = \Delta_1 - \Delta_2$$

where Δ_1 = performance of an absorptive barrier and grass sided cuttings

Δ_2 = reflective barrier correction

The following relationship is given for absorptive barriers:

$$\Delta_1 = 7.75 \log(5.2 + 203\delta) \quad \text{for } 0 < \delta < 2.5 \text{ m} \\ = 21 \quad \text{for } \delta > 2.5 \text{ m}$$

where δ is the path difference (m) determined for a source at the head of the rail.

$$\Delta_2 = 0 \quad \text{for } D > 20 \text{ m} \\ = 5 - 0.25D \quad \text{for } 1 \text{ m} < D < 20 \text{ m} \\ = 4.8 \quad \text{for } D < 1 \text{ m}$$

where D is the distance between the relevant near rail and the barrier.

Housing development can also be a source of additional attenuation. These can be treated as a composite barrier.³ Alternatively, some simple rules of thumb have been reported in Ref. 4 where an A-weighted noise level reduction of 8 dB is quoted for a row of semidetached houses. Subsequent rows provide an additional 4-dB reduction in noise level for each row.

High development near a railway line obviously provides shielding to other development behind it but creates other problems in that high stories overlook the railway and are difficult to shield with lineside barriers. Also in situations where such development is on both sides of the track, multiple reflections can give rise to problems.

4.5 Reflection Correction Δ_{refl}

Certain legislation requires prediction of the noise level at, or immediately in front of, the facade of a property.

This requires an additional correction due to the presence of the facade. Most models include a +3-dB correction relative to the free-field A-weighted noise level.

5 MODIFICATION TO REFERENCE NOISE LEVELS

The reference situation is a train operating on continuously welded rails supported by concrete sleepers on ballast. A number of variations to that reference situation are in use and their effect, which should be included in the reference noise level term, is discussed below.

5.1 Jointed Track

As the wheels traverse a joint, there will be an increase in noise level. The maximum passby A-weighted sound pressure level, when close to the track, will increase by approximately 5 dB. Since the noise profile will now consist of a number of "spikes," the effect will be less for A-weighted SEL, and an increase of about 2 dB is more appropriate. These increases can also apply in close proximity to switches and crossings. Jointed track will have no effect on the power unit noise from a diesel locomotive.

5.2 Wooden Sleepers

The effect of wooden sleepers appears to be within the variability of measured noise levels for supposedly identical conditions. No further corrections should be made for either rolling noise or diesel locomotive power noise.

5.3 Slab Track

This is an alternative track design where the ballast is replaced by a concrete slab to form the track foundation. It is not in common use on surface railways, but measurements have indicated an increase in A-weighted noise level relative to the reference condition of between 2 dB and 10 dB for rolling noise.

5.4 Elevated Structures

No change to the reference A-weighted noise level is required for a train on an embankment. Any change in received noise level compared to the flat site situation is a consequence of reduced attenuation by the ground. Surveys of concrete and steel structures have concluded that steel structures tend to be noisier than concrete structures, and the worst situation is for a steel structure with the track fastened directly to it, that is, there is no ballast. In this situation an enhancement in A-weighted noise level of up to 16 dB is possible relative to the reference situation. Where a concrete structure is used, direct fixation can give increases of up to 10 dB, but when the design includes ballasted track and a solid parapet (to act as a barrier) that increase may only be of the order of 1 dB. The addition to the A-weighted noise level results from the supporting structure acting as a secondary sound source.

6 RAIL SYSTEM NOISE ASSESSMENT

6.1 European Practice

A recent study,⁹ funded by the European Commission, reviewed European national railway noise legislation and indicated an almost common use of external L_{Aeq}

for assessing environmental noise from railways. Three Nordic countries use a 24-h value plus L_{Amax} , and the Nordic railway noise prediction model has been developed to predict both of these metrics.¹⁰ The Netherlands uses a three-time-period (day, evening, night) assessment criteria and other countries use criteria based on a day–night split. It is common for those countries with railway noise legislation to have national railway noise prediction models. This is certainly the case for the United Kingdom, France, the Netherlands, Germany, and Switzerland.

The legislative limits *are not used* to determine a maximum level that must not be exceeded but are usually part of national noise insulation regulations for new infrastructure schemes where limits are set that, when exceeded at residential property adjacent to the railway, means that the property is eligible for additional sound insulation.

Each country has different limit values in its legislation, and where separate time periods are used these also differ from country to country. In order to obtain reliable statistics on noise exposure from transport in Europe an Environmental Noise Directive⁷ requires mapping to be carried out in terms of the day–evening–night noise level L_{den} . No European country uses L_{den} as part of national legislation, therefore all member states will be required to introduce new prediction methodology to fulfill the requirements of the new European legislation.

European Union projects HARMONOISE¹¹ and IMAGINE¹² have been initiated to develop harmonized models for road, rail, and industrial noise. It is expected that models from these projects will eventually replace national models in preparation of the necessary maps.

6.2 Practice Elsewhere

In the United States noise impact estimates are made using either Federal Transit Administration (FTA) or American Public Transit Association (APTA) criteria. FTA criteria¹³ are based on absolute L_{eq} values, whereas APTA guidelines¹⁴ are written in terms of maximum passby A-weighted sound pressure level. Prediction models have been developed in Japan for the Shinkansen lines considering lower car parts, concrete bridge structures, and aerodynamic noise from the upper car and pantograph as separate noise sources.¹⁵ It is common in Australia to assess railway noise in terms of both L_{eq} and L_{max} . The Nordic prediction model is used in these cases. More details on assessment criteria and legislative limits can be found in Chapters 25 and 34.

7 RAIL SYSTEM NOISE CONTROL OPTIONS

7.1 Noise Control at Source

Although received noise level (L_{eq}) is dependent on number of trains, train speed, train length, and distance from the track, its change is not particularly sensitive to these parameters, especially when the considerations of a commercially competitive operating railway have to be taken into account. Effective noise control can

only be achieved by reducing the noise at source or by use of barriers to noise propagation.

Rolling noise, the main contributor to rail system noise, is the sum of wheel-radiated noise and track-radiated noise. The balance between these sources, given in the equation below, varies with detailed design of wheel and track and operating conditions:

$$L_{TOT} = 10 \log(10^{L_{WHEEL/10}} + 10^{L_{TRACK/10}})$$

where L_{TOT} = total rolling noise

L_{WHEEL} = wheel-radiated noise

L_{TRACK} = track-radiated noise

This relationship is important when considering the control of the A-weighted noise level. If

$$L_{WHEEL} - L_{TRACK} \geq 10 \text{ dB},$$

track treatments in isolation will be ineffective. If

$$L_{TRACK} - L_{WHEEL} \geq 10 \text{ dB},$$

wheel treatments in isolation will be ineffective.

The flowchart for rolling noise generation, discussed in Chapter 93, identifies areas where measures can be applied to reduce either both wheel and track noise (reduction of force in contact zone/increase propagation losses) or wheel and track noise separately by using low noise components in wheel and track designs. Chapter 93 has given an overview of noise mitigation options and these are summarized below.

7.1.1 Smooth Wheels Smooth wheels and rails can reduce both the wheel and track components of rolling noise. Wheel roughness is controlled by the type of braking used, and for some years the use of disk brakes on passenger vehicles has shown a reduction in A-weighted noise level of about 8 dB when compared to the noise from cast-iron tread braked vehicles at the same speed.

Brakes made of composite materials can give noise characteristics similar to disk-braked wheels on passenger vehicles, although because of higher wheel temperatures during braking, leading to higher residual stresses, wheel cross-section optimization will not be an option.

The general trend on mainland Europe is to use cast-iron tread brakes on freight vehicles; thus the wheels are considered to be “rough” and the vehicles “noisy.” An initiative currently being undertaken by the Union of International Railways (UIC) aims to replace those cast-iron brake blocks with ones made of composite materials.

The development of direct replacement composite brake blocks is the subject of a current EU 5th Framework Project.

Current knowledge is such that reduction of wheel roughness levels below those found on disk-braked wheels will not be achievable in the short to medium term. Therefore, where a vehicle design currently includes disk or composite brake blocks, any noise

benefit from a further reduction of wheel roughness should not be expected.

It should further be pointed out that where cast-iron tread brakes are used, the service roughness levels are achieved quickly and smoother surfaces to disk-braked wheel roughness levels are not achievable even through maintenance no matter how frequent.

7.1.2 Smooth Rails Smooth rails are essential for a low-noise railway, and the formation of corrugations can increase rolling A-weighted noise levels from disk-braked stock by up to 20 dB. There are no validated models for rail roughness growth, and rail roughness is usually controlled through maintenance by grinding. Rail roughness has to be higher than wheel roughness before noise reduction will result from grinding, and this is certainly the case with corrugated rail.

7.1.3 Low-Noise Wheels One of the objectives of the Silent Freight Project¹⁶ (EU 4th Framework Brite Euram Project BE95-1238) was to develop cost-effective low-noise wheel designs. Options considered were:

- Optimization of the cross section to minimize axial response due to radial forces
- Reduction of wheel diameter
- Additional damping
- Screening of the web

The Silent Freight Project showed that when compared to the noise produced by a standard ORE/UIC 920-mm-diameter wheel, reductions in wheel-radiated A-weighted noise levels of about 7 dB (860-mm-diameter shape optimized wheel with tuned absorbers) and 9 dB (860-mm-diameter shape optimized wheel with shields on the web) could be obtained.

7.1.4 Low-Noise Tracks A parallel project Silent Track¹⁷ (EU 4th Framework Brite Euram Project BE96-3017) developed a number of low-noise track designs incorporating:

- Use of stiff rail pads
- Rail-tuned absorbers
- Reduction of rail foot width
- Optimized sleeper

The Silent Track Project showed that compared to a track with standard soft rail pads a reduction in track-radiated A-weighted noise level of between 5 dB and 6 dB could be obtained from the use of tuned absorbers on the rail.

Because of the need to reduce dynamic fatigue loads in sleepers and track support structures, softer rail pads are becoming more common. Softer rail pads also limit rail roughness growth and are thus beneficial from that point of view. The desire for high rail pad stiffness for noise reasons is therefore in conflict with track fatigue requirements. Interestingly the absolute noise level when using tuned rail absorbers is virtually independent of the rail pad stiffness.

7.2 Bogie Shrouds and Low Trackside Barriers

As discussed in Chapter 93, where it is possible to achieve an overlap of the bottom of the shroud and top of the barrier, an A-weighted noise level reduction of up to 10 dB can be achieved.¹⁸

In a study as part of Silent Freight¹⁶ and Silent Track,¹⁷ where an overlap was not possible due to international gauging restrictions, this A-weighted noise level reduction was limited to 3 dB to 5 dB.

These forms of treatment can be effective, but there are a number of maintenance and inspection issues that need to be overcome before they can be implemented.

7.3 Noise Barriers

Section 3.4 of this chapter has indicated how the effectiveness of noise barriers can be incorporated into a noise prediction model. For a barrier to be effective, the receiver needs to be in the shadow zone, that is, below the straight line drawn from the source position through the top of the barrier.

Measurements indicate a maximum A-weighted noise level reduction for a plain vertical reflective barrier to be in the region of 15 dB, although this requires the barrier to have a height of 3 m more than the source. That benefit can be increased by about 5 dB with sound-absorbing material in the side of the barrier facing the railway. The European Rail Research Institute carried out a review of noise barrier design¹⁹ and concluded that this was the most effective way of increasing the noise reduction of a plain vertical reflective barrier. At that time other changes to barrier design offered little effective benefit.

7.4 Cost-Effective Noise Mitigation

A software tool has been developed in the STAIRRS project (strategies and tools to assess and implement noise reducing measures for rail systems), which was funded through the EU's 5th Framework Competitive and Sustainable Growth Programme. Figure 4, taken from the final report,²⁰ shows a relative comparison of cost and effectiveness for a number of mitigation options when applied to the European network. This shows that noise reduction at source, as discussed above, can be more effective and less costly than

Figure 4 Cost-effectiveness analysis of noise reduction options. (From Ref. 20.)

an option consisting of high barriers alone. Thus, it will be worthwhile to invest more time and effort into developing noise reduction at source to give designers more options in implementing low-noise railway systems.

1 INTRODUCTION

Noise barriers have become a very common feature of urban landscapes. For example, in the United States over 1200 miles of noise barriers were constructed in the year 2001 alone. Any form of solid obstacle between source and receiver can comprise a noise barrier. A barrier can reduce the noise in residential areas if it is well designed. Barriers should be impervious to sound without cracks or holes and of sufficient height to provide sufficient noise attenuation. Barriers are most effective if placed near to the source of noise or the receiver and are generally ineffective for low-frequency noise. In some instances, sound-absorbing material is placed on or in the source side of the barrier to reduce noise buildup there. The majority of barriers are installed in the vicinity of transportation and industrial noise sources to shield nearby residential properties. Unlike building insulation, noise barriers are designed to protect the external as well as the internal environment at a dwelling. Noise barriers are cost effective only for the protection of large areas including several buildings and are rarely used for the protection of individual properties. Noise barriers of usual height are generally ineffective in protecting the upper levels of multistory dwellings.

2 NOISE BARRIER PERFORMANCE INDICES

In the past two decades environmental noise barriers have become the subject of extensive studies, the results of which have been consolidated in the form of national and international standards and prediction models.¹⁻⁵ Some unresolved problems still remain, and these mainly relate to the degradation of the noise

barrier performance in the presence of wind and temperature gradients, atmospheric turbulence, temporal effects from moving traffic, vehicle composition and speed, aesthetic quality of barriers, and their environmental impact.⁶ An extensive guide to the acoustical and visual design of noise barriers can be found in some textbooks and design manuals.^{7,8}

The performance of a barrier in shielding a receiver from a noise source can be described by the term *barrier attenuation* (Att), which is defined by

$$\text{Att} = -10 \log_{10} \left(\frac{|p_{\text{bo}}|^2}{|p_{\text{ff}}|^2} \right) \text{ dB} \quad (1)$$

where p_{ff} is the sound pressure in free field at the receiver, and p_{bo} is the sound pressure in the presence of the infinite barrier in a semiinfinite configuration, that is, when there is no ground and the lateral length of the barrier is infinite. Therefore Att gives the most basic performance of a barrier in blocking the direct sound from reaching the receiver and is useful when comparing the performance of different barriers without the complications of influences from other propagation effects. The use of the negative sign in the right-hand side of the equation is based on the convention that a reduction in sound pressure level is defined as a positive attenuation.

Usually a barrier is placed on ground and is of finite length. Hence, a more practical performance index is the *excess attenuation* (EA):

$$\text{EA} = -10 \log_{10} \left(\frac{|p_b|^2}{|p_{\text{ff}}|^2} \right) \text{ dB} \quad (2)$$

where p_b is now the sound pressure at the receiver with the barrier in its actual configuration—erected above ground and of finite length.

The use of the free-field sound pressure p_{ff} as the reference in Att and EA is convenient for theoretical calculations. In practice, it is sometimes difficult to determine the free-field sound pressure. A more direct way of describing the performance of a barrier is to measure the reduction of the sound pressure level before and after the erection of the barrier. This is known as the *insertion loss* (IL):

$$IL = -10 \log_{10} \left(\frac{|p_b|^2}{|p_{w/o}|^2} \right) \quad \text{dB} \quad (3)$$

In this case the reference sound pressure $p_{w/o}$ is the sound pressure at the receiver before the barrier is built. Usually, this includes the ground effect (see Chapter 5) and can be predicted using the models detailed in Chapter 58. IL is therefore a direct indicator of the actual benefit that a barrier could bring to a receiver in a specific site. Where there is no ground effect and the barrier is of infinite length, IL is equal to Att.

The above three indices are the preferred indices for barrier performance because they are consistent with indices used in other areas of acoustics. There are other terms that have also been used to describe barrier performance. Two common ones are *noise reduction* (NR) and *transmission loss* (TL). The noise reduction of a barrier is defined in a similar way to IL, but since the term is used also in building acoustics to describe the sound pressure level reduction provided by a partition between two rooms the use of noise reduction could cause confusion. The definition of transmission loss of a barrier can be even more confusing, since TL is used both in building acoustics to describe the reduction in sound intensity level through a partition made of particular materials, and also in outdoor sound propagation as the attenuation relative to the sound pressure at a reference position (usually 1 m) from the source. Hence the recommendation is to use Att, EA, and IL to describe barrier performance.

In 1996, the International Organization for Standardization (ISO) published ISO 9613-2¹ that describes a general method of calculation of attenuation of sound during propagation outdoors. This standard has been adopted widely for practical predictions of the noise barrier insertion loss using a modified form of the empirical formula:

$$IL = 10 \log_{10} \left[3 + \left(C_2 \frac{\delta_1}{\lambda} \right) C_3 K_{\text{met}} \right] \quad (4)$$

where $C_2 = 20$ and includes the effect of ground reflections; $C_2 = 40$ if ground reflections are taken into account elsewhere. C_3 is a factor to take into account of a double diffraction or finite barrier effect, $C_3 = 1$

for a single diffraction, $\delta_1 = (r_s + r_r) - r_0$, and

$$C_3 = \frac{\left[1 + \left(\frac{5\lambda}{w} \right)^2 \right]}{\left[\frac{1}{3} + \left(\frac{5\lambda}{w} \right)^2 \right]}$$

for double diffractions, $\delta_1 = (r_s + r_r + w) - r_0$. In these expressions r_0 is the direct distance from the source to the receiver in the absence of the barrier, r_s is the distance from the source to the top barrier edge, r_r is the distance from the top barrier edge to the receiver, w is the width of the barrier, and λ is the acoustic wavelength. The term K_{met} in Eq. (4) is a correction factor for average downwind meteorological effects, and is given by

$$K_{\text{met}} = \exp - \frac{1}{2000} \sqrt{\frac{r_s r_r r_0}{2\delta_1}} \quad \text{for } \delta_1 > 0$$

$$= 1 \quad \text{for } \delta_1 \leq 0$$

It can be seen that the formula reduces to the simple formula $IL = 10 \log_{10}(3 + 20N_1)$ when the barrier is thin, there is no ground, and when meteorological effects are ignored. This formula is identical to that suggested by Tatge⁹ and depends only on the Fresnel number, $N_1 = 2\delta_1/\lambda$, in which the path difference is $\delta_1 = (r_s + r_r) - r_0$.

3 ATMOSPHERIC EFFECTS ON NOISE BARRIER PERFORMANCE

The analytical and empirical formulas for barrier attenuation, which are presented in Chapter 58, are mostly derived from theoretical considerations or scale-model experimental data of edge diffraction under laboratory conditions. When barriers are used in the field, they are inevitably affected by the presence of ground and the meteorological condition of the atmosphere. Atmospheric turbulence, for example, can scatter substantial amount of sound energy into the shadow zone of a barrier. Generally, the field performance of a barrier is lower than predicted particularly at receivers where the predicted attenuation is high. In most standard calculation methods the barrier attenuation is limited to 20 dB for a single barrier and 25 dB for a double barrier.

The effect of ground on barrier insertion loss can be included by the methods introduced in Chapter 5. The effect of the meteorology is more difficult to account for, partly because of the complex theory involved but also because of the lack of detailed and rigorous enough meteorological data for the study. In most field studies, only simple meteorological data such as wind speed, direction, and temperature have been logged at a single position, and details of the position-dependent sound speed profile and turbulence structure were not determined. Scholes et al.¹⁰ measured the effect of a full-size noise barrier under different weather

Figure 1 Variation of sound pressure level behind a barrier in the field. (From Scholes et al.¹⁰)

conditions for the source height of 0.7 m. Although the meteorological data recorded was not sufficient to make the findings conclusive, the possible changes in field performance can still be seen when the measured sound pressure level behind the barrier was plotted against the recorded vector wind speed, as shown in Fig. 1. More than 15-dB variation can be seen at 4 kHz within a range of ± 5 m/s vector wind speed.

It should be noted that there are two influences of meteorological conditions on barrier attenuation. The first results from the refraction of the diffraction path due to the vertical sound speed gradient. If the gradient is positive, that is, sound speed increases with height, then the sound path will be refracted downward and the result is an effective reduction of the diffraction angle, and a corresponding reduction in the barrier attenuation. A simple empirical estimate of the effect of typical downward refraction condition is provided by the K_{met} factor, which is independent of frequency, in barrier attenuation formula (4).

The second influence is the scattering of the sound energy by atmospheric turbulence, such that higher level of sound energy penetrates the shadow zone than would be from diffraction alone. Both the sound speed profile and the atmospheric turbulence are dependent on the atmospheric temperature and wind. With typical sound speed profiles encountered outdoors, the refraction effect is generally small at a short range from the barrier. For example, with a 3-m high barrier, a source-to-barrier distance of 10 m, and a receiver-to-barrier distance of 100 m, the K_{met} correction gives a reduction of barrier attenuation of less than 1 dB. The atmospheric turbulence scattering

Figure 2 Measure and predicted excess attenuation at a receiver 18 m from 2.44 m wide, 2.55 m high barrier showing the effect of atmospheric turbulence. Source is 8 m from barrier.

is, on the other hand, highly significant especially deep in the shadow zone where the diffracted energy is weak. Figure 2 shows the time-averaged excess attenuation EA (dB), taken from Forssén and Ögren, measured on a 2.44-m wide, 2.55-m high barrier under light turbulence (light wind, about 1 to 3 m/s) and strong turbulence (strong wind, about 4 to 7 m/s) conditions. The source is 8 m from one side of the barrier and 2.9 cm above ground. The receiver location chosen is 18 m on the other side of the barrier and 1.25 m above ground. The turbulence effect was predicted by means of a secondary source model.¹¹

It can be seen clearly that the effect of turbulence is strongest at receivers where the attenuation is highest. Generally, the reduction in attenuation due to turbulence is stronger deeper into the shadow zone at higher frequencies and at longer ranges. Furthermore, with strong turbulence (wind 4 to 7 m/s), a reduction of more than 5 dB at a receiver 18 m away can be seen in the attenuation even at places where the no-turbulence attenuation is low. It should be noted that Fig. 2 shows the time-averaged values. Scattering by turbulence can produce large random variations of sound pressure level with time. Unfortunately, there is no reliable simple formula that can be used to estimate

the effect of turbulence on barrier attenuation. It should also be noted that although atmospheric turbulence is dependent on wind, it is equally dependent on temperature fluctuations in the atmosphere. Strong turbulence can still be found under no-wind situations because of large thermal buoyant instabilities. Hence measuring wind speed itself is not sufficient to fully characterise atmospheric turbulence.

The influence of uncertainties in ground characteristics and meteorological conditions can explain why, generally, the field performance of barriers, especially those with complex shapes, is found to be lower than predicted. For example, Watts¹² conducted an extensive field trial of a multiedge noise barrier at three motorway sites in the United Kingdom. Watts found that the improvement provided by the multiedge barrier in the field over a conventional thin barrier of the same height was close to that predicted when the A-weighted barrier attenuation is less than about 12 dB. The improvement in the field, however, was found to be insignificant for greater values of attenuation in contrast to the continuous improvement predicted by theory. More recent experiments by Watts¹³ have demonstrated that ± 2 -m/s fluctuations in the wind velocity can result in 5 to 7 dB degradation in the spectral values of the insertion loss of a noise barrier for frequencies above 1000 Hz. In this work a source and receiver were installed on the opposite sides and 1.0 m away from the top of a 2.0-m T-shaped reflective noise barrier and the sound pressure levels and the wind speed were recorded for a period of time.

It is clear that the study of barriers, especially those with high performance, should also consider elements of outdoor sound propagation, including the barrier effects on the wind velocity profile, to obtain a reliable estimate of the performance of a barrier in the field.

4 NOMOGRAMS AND COMPUTER PROGRAMS

The physical principles related to the diffraction of the sound by a noise barrier, discussed in detail in Chapter 58, form part of broader sound propagation prediction standards for specific types of noise sources, that is, road traffic, railway, airport, and industrial sources. Some of these formulas based on the Maekawa prediction method,¹⁴ and on the method proposed by Kurze and Anderson.¹⁵ Different predictive standards were adopted nationally, but increasingly these standards are showing some conformity and are condensing into smaller numbers with continental or worldwide acceptance.

An internationally adopted method of predicting the attenuation of noise barriers is given in the ISO 9613-2 (1996)¹ which is detailed in Section 2. Figure 3 plots the insertion losses as a function of the path length difference, δ_1 , calculated using the ISO 9613-2 for a single barrier (Fig. 3a) and for an earth berm of an equivalent height (Fig. 3b). In these calculations the top of the earth berm is assumed to be 1.0 m wide and the meteorological effects are ignored ($K_{\text{met}} = 1$).

The formulas provided in this standard are incorporated in several software packages for community

noise prediction, including Cadna-A¹⁶ and SoundPLAN.¹⁷ These products also include several national prediction models, for example, the American TNM, Scandinavian Nord 2000, British CRTN and CRN, French NMPB, and Japanese Road Model B, which also account for the noise barrier effect. A particular recent and comprehensive Nord 2000 method is based on the complete separation of sound emission and sound propagation phenomena. It accounts for the atmospheric and ground effects around a barrier and allows nonflat terrain profiles and nonstandard barrier shapes to be considered.¹⁸

In the last 20 years the boundary element method (BEM) has been used commonly to model the performance of noise barriers with the complex top edge and in the presence of absorbing/impedance surfaces. To date, it is only really effective, over the full frequency range of interest, for outdoor ground surfaces that are essentially one dimensional, meaning that there is some horizontal vector in which direction there is no change in surface elevation or in acoustical properties. The method requires the discretization of the noise barrier surfaces and the surfaces of nonuniform impedance. Practical applications of the method are limited to two-dimensional problems of several thousands elements. A typical size of the element is $\lambda/10 - \lambda/5$, where λ is the acoustic wavelength. Via conversion of the three-dimensional problem to a sequence of two-dimensional problems using a partial Fourier transform, the method can be used to produce predictions for a point or incoherent line source of sound.¹⁹ (Duhamel, 1996). In its original form the boundary element method is limited to modeling homogeneous quiescent atmospheres, so that wind and temperature gradient effects are not modeled. A comprehensive summary of the existing BEM models and available software for the predictions has been compiled by Chandler-Wilde.²⁰

Alternative methods for the prediction of noise barrier performance in the presence of wind and temperature gradients include the parabolic equation (PE) method and the fast field program (FFP) method. These methods are detailed in the textbook by Salomons.²¹ The PE method is well-suited for medium- and long-range sound propagation predictions in the presence of slowly changing, realistic wind speed profiles. The original PE method is a one-way sound propagation method and does not include more complex interference effects, for example, the diffraction of sound around multiple edge noise barriers. The FFP method allows two-way propagation and is suitable for the prediction of sound propagation in vertically stratified media with piecewise constant sound speed profiles. Recently, this method has been combined with the BEM to model the complex diffraction effects.²²

5 NOISE BARRIER DESIGN

A major rule for the noise barrier design is to install it as close as possible to the noise source so that the distance to the source is less or equal to the barrier height $r_s \leq H$ (see Fig. 3a). Alternatively, the barrier

Figure 3 Predicted values of the attenuation provided by (a) a plane screen and (b) a 1 m wide earth berm. (From ISO 9613-2, section 7.4.¹)

can be placed close to the receiver, but in this case the barrier will be effective only for low receiver heights. Where an earth berm or cutting is present in the vicinity of the source, any additional screen should be installed to ensure the maximum value of the path difference, δ_1 . The acoustical efficiency of such a noise barrier can be predicted using the procedures explained previously or determined in situ using the standard

methods detailed in ISO 10847:1997² or in American National Standards Institute (ANSI) S12.8-1998.³

5.1 Transmission of Sound through the Barrier Material

An essential criterion for selecting noise barrier material is to ensure that the noise contribution transmitted through the barrier material is insignificant

Table 1 Categories for Airborne Sound Insulation Defined in EN1793-3:1997

Category	DL_R (dB)
B0	Not determined
B1	< 15
B2	15 to 24
B3	> 25

in comparison with the contribution from the sound diffracted over the barrier edges. The European standard EN 1793-3⁴ defines the procedure for measuring the intrinsic characteristics of airborne sound insulation performance and specifies four categories B0 to B3, which are based on the value of single-number rating of airborne sound insulation performance, DL_R . These categories are summarized in Table 1.

A basic requirement for the material and structure of a noise barrier is that for a given noise source spectrum the difference between the broadband and sound pressure levels of the transmitted, L_t , and the diffracted, L_d , noise components should exceed 10 dB, that is,

$$L_d - L_t \geq 10 \text{ dB} \quad (5)$$

In the case of a long, continuous, impervious noise barrier assembly without any structural defects, ISO 9613-2¹ specifies a minimum surface density of 10 kg/m². This is the minimum value required for any screening obstacle to be considered as a noise barrier. An alternative recommendation defines the minimum surface density (m) of the noise barrier material²³ by

$$m = 3 \times 10^{\text{Att}-10/14} \text{ kg/m}^2 \quad (6)$$

where $\text{Att} > 0$ dB is the predicted attenuation of the direct sound by a "massive barrier," that is, where there is only diffracted sound. The value of m predicted by expression (6) excludes the contribution from any structural elements and from the barrier foundation. According to expression (6) the minimum surface density required to achieve 20-dB attenuation is $m = 15 \text{ kg/m}^2$. The range of the surface densities of practical barrier materials varies from 4.4 kg/m² for a 1.59-mm aluminum sheet to 244 kg/m² for 100 mm of dense concrete. Typical barrier materials include metal, aluminum, pressure preservative treated timber, engineering bricks, or masonry blocks and their combinations. Almost half of the noise barriers constructed in North America until now are made of concrete. Transparent noise barriers are common in Europe and the Far East. These barriers are often made of Plexiglas, acrylic, or safety glass.

5.2 Absorption of Sound by the Barrier Material

In some applications the surface of a noise barrier is treated with an acoustically absorbing material to reduce the reflected acoustic energy. This requirement

**Figure 4** Effect of multiple reflections on the acoustical performance of a road noise barrier.

may be important if the barrier is close to the noise source, as illustrated in Fig. 4, or where two parallel noise barriers are closely installed. The absorbing barrier surface reduces the effect of multiple reflections. When high-sided vehicles, for example, lorries, buses, or trains, pass close to a barrier, multiple reflections increase the level of the diffracted component, L_d . The potential increase in the level of the diffracted component has been estimated in several studies.²⁴⁻²⁶ In a particular case, where a rigid, 1.5-m high barrier was installed 1.0 m away from a passing railway carriage, the maximum predicted improvement in the average insertion loss due to the absorbing barrier treatment was 14 dB.²⁵ Another study by Watts and Godfrey²⁶ found that absorbing treatment on a 3.0-m high roadside noise barrier had an insignificant effect on barrier efficiency when the barrier was installed 5.6 m from the edge of a busy motorway. It should be generally understood that the value of the degradation can vary from site to site and would depend largely on the proximity of the barrier to the road, barrier elevation, position of the receiver, quality of the absorbing treatment, and the type of the ground near the barrier.

The quality of the absorbing treatment on noise barriers is regulated by the European standard EN1793-1.⁴ The standard defines five categories, A0 to A4, which are related to the measured value of the single number rating of sound absorption performance, DL_{α} . These categories are summarized in Table 2. It is generally accepted that noise barriers with high surface absorption offer superior performance only when the distance between a noise barrier and the source is less or comparable to the barrier height.

Examples of absorbing barrier assembly are illustrated in Fig. 5. Figure 5a shows a typical absorptive noise design consisting of prefabricated, perforated metal panels between two steel sections, which are secured into a solid concrete foundation. It is common to fill the panels with a mat of fibrous absorber (e.g., rockwool or fibreglass), the face of which is

Table 2 Categories of Absorptive Performance Defined in EN 1793-1

Category	DL_{α} (dB)
A0	Not determined
A1	< 4
A2	4 to 7
A3	8 – 11
A4	> 11

treated with a protective, hydrophobic porous membrane. A typical thickness of the mat is between 50 and 100 mm. Timber enclosures filled with fibrous absorbers can provide a cheaper alternative to the relatively expensive perforated metal panels.

In some countries it is common to use 50- to 150-mm slabs of consolidated granular materials or woodfibre as shown in Fig. 5b. The corrugated surface of the porous slabs improves the absorption and diffusion of sound at oblique angles of incidence. The slabs are securely fastened using steel bolts or threaded bars that can be cast into the concrete backing. A typical height of these barriers is largely determined by the site conditions and by the required value of insertion loss. Practical barrier heights tend to vary from 2 to 4 m, which are capable of achieving a 10- to 15-dB insertion loss at low receiver levels.

Figure 5 Two types of absorbing treatment for barriers: (a) perforated panels filled with fibrous absorber and (b) slabs of consolidated granular material or wood fiber.

The length of a noise barrier should considerably exceed the barrier height. An empirical rule adopted by the U.S. Federal Highways Administration (FHA) suggests that a barrier should be long enough such that the distance between the receiver and a barrier end is at least four times the perpendicular distance from the receiver to the barrier along a line drawn between the receiver and the road. An alternative rule is to ensure that the angle subtended from the receiver to a barrier end should be at least 80 degrees, as measured from the perpendicular line from the receiver to the roadway.

5.3 Effect of the Barrier Shape

An improvement of the barrier efficiency can also be achieved by modifying the shape of the upper edge. The results of numerical modeling and full-scale tests, for example, Crombie et al.,²⁷ Duhamel,¹⁹ Watts and Morgan,²⁸ and Ishizuka and Fujiwara,²⁹ suggest that T-shape barriers and multiple-edge noise barriers can provide a 2.0- to 2.5-dB improvement of the broadband insertion loss without apparent increase of the barrier height.²⁸ A comprehensive summary of the efficiency of noise barriers of different edge shapes can be found in the study by Ishizuka and Fujiwara.²⁹ This work shows that a complex noise barrier edge, for example, a Y-shape barrier or barrier with a cylindrical edge, can yield a 4.0 to 5.2-dB improvement in the insertion loss with respect to that for a plain barrier of the same height of 3.0 m. This is important when the increase in the barrier height is not practical or impossible. A useful diagram from this reference illustrating the change in the mean insertion loss relative to a standard 3 m high, plane screen noise barrier is provided in Fig. 6.²⁹

In the Far East, particularly in Japan, cantilever barriers of parabolic shape are used widely to shield residential areas from noise emitted by elevated highways. These barriers curve inward over the roadway and are typically between 8.0 and 15.0 m in height, to maximize their efficiency (see Fig. 7). In a typical arrangement one barrier is made of a transparent material, for example, Perspex, to provide natural lighting conditions. All the internal surfaces of the nontransparent barrier are designed to be sound absorbing to control multiple reflections within the barrier corridor.

Earth berms (earth mounds) are used in rural and semirural locations as an alternative ecodesign to or in conjunction with noise barriers. These structures are attractive because they are easy to blend with the landscape and require little maintenance. However, earth berms require much more space than a vertical barrier of equivalent acoustical performance. The standard method of prediction of the acoustical efficiency of an earth berm is detailed in the ISO 9613-2.¹ The acoustical efficiency of a berm is determined by the path length difference between the noise source and receiver, the shape of the top edge, and by the effect of the porous soil of which the berm is constructed. It is generally agreed that when an absorbing surface is introduced to a wide earth berm, some improvement in insertion loss in the higher frequency range can be expected, particularly when the receiver and the source are in the proximity of the berm; see Daigle, page 146.⁷

Figure 6 Comparison of acoustical performance of noise barriers of various shapes predicted using the source spectrum defined in EN 1793-3. The numerical labels indicate the relative change in the mean insertion loss relative to a 3-m plane screen. (From Ishizuka and Fujiwara.²⁹)

This report suggests that the efficiency of the absorbing surface of the earth berm is reduced if the wedge angle of the berm is greater than 45° . The acoustical performance of the earth berm with a flat, grass-covered top can be similar to that of a plane rigid barrier of equivalent height.⁷ Mounting of a plane barrier on the top of an earth berm may not offer any benefits due to lost positive effect of its absorbing surface.

Alternative sustainable barrier designs (ecodesigns) include planting that has been used for many years, particularly in the Netherlands and Denmark, to blend a man-made barrier into the surrounding landscape. Present ecobarrier designs are based on successful combinations of living and man-made materials that include thatch barriers, willow-weave wall, and stack and crib biobarriers. Concrete, timber, masonry, and steel support structures can also be used to support vegetation including flowers and bushes. Some ecobarrier designs also incorporate porous absorbing materials that can control the reflections from the barrier surface. More

Figure 7 Cantilever noise barrier system on a Japanese highway.

details of these can be found in the textbook by Kotzen and English.⁸ Some of these barriers are designed to be self-sufficient, require little maintenance, and can have

Figure 8 Typical arrangements of (a) the escape door and (b) a safety gap.

the life span of 25 years or more. An ecobarrier offers a 5- to 6-fold saving of space in comparison with the case of an earth berm and provides sustainable solutions to noise abatement, screening, and fencing, both in urban and rural situations.

5.4 Air Gaps, Safety, and Maintenance

In addition to the basic requirements for the acoustical performance of a barrier, there are several non-acoustical characteristics that should be satisfied. These characteristics relate to wind and static loading, safety in collision, dynamic load from snow clearance, resistance to brush fire, danger of falling debris, light reflection, means of escape, transparency, and impact of flying stones. Relevant test methods are detailed in the EN 1794-1 and EN 1794-2.⁵

Long sections of noise barrier require regular access points for maintenance and emergencies. It is common to provide escape doors or gaps at intervals of a few hundred metres. The Highways Agency in the United Kingdom recommends the installation of safety doors or channels at intervals of not more than 200 m. The width of the access routes must be sufficient to enable delivery of the first aid equipment including stretchers. Examples of noise barrier escape routes are illustrated in Figs. 8a and 8b, respectively. Doors and frames must be accurately fitted and properly sealed to

minimize the leakage of noise through possible gaps. Escape channels should include an overlap section that is typically lined with acoustically absorbing material to ensure that the acoustical efficiency of the noise barrier is not compromised by the discontinuity. The length of the overlap is typically selected as a 2:1 or 3:1. To reduce line-of-sight propagation phenomena the overlap is designed so that the ratio of the overlap length, L_0 , to the overlap width, W_0 (see Fig. 8b), is typically 1:2 or 1:3.

The effects of gaps on barrier performance has been studied by Don et al.,³⁰ Watts,³¹ and Herman and Clum.³² Gaps in the continuous barrier surface can develop as a result of poor workmanship, degradation of the barrier material due to the weather and elements, vandalism, and as a result of road accidents. Watts demonstrated that the structural defects in wooden barriers could cause a 9-dB reduction in the predicted value of the insertion loss in the vicinity of the barrier.³¹ Herman and Clum analyzed overlap barrier gaps both experimentally and numerically.³² Their work shows that overlapping gaps between two reflective barriers can result in a 5- to 11-dB reduction in value of the insertion loss predicted immediately behind the barrier. Typically, a degradation of 1 to 5 dB can be expected in the performance of absorbing

barriers. The effects of the overlap gap tend to reduce and become negligible at distances from the barrier, which considerably exceed the width of the overlap. In countries with cold climates, for example, in Finland or Russia, controlled gaps are created deliberately at the bottom on a noise barrier to avoid the damage due to frost and snow. These gaps can cause a 3-dB degradation in the barrier insertion loss.⁸ This value of degradation becomes negligible at greater receiver distances.

5.5 Effects of Traffic Type, Composition, and Speed

The traffic composition and speed can affect the broadband and spectral performance of a noise barrier as a result of the variation in the source spectrum, source type, and position. This detailed aspect of the performance of noise barriers is not well understood and is the subject of ongoing research. Although these factors have a marginal influence on the prediction of the barrier attenuation in terms of the time-dependent noise indices (L_{eq} and L_{10}) used to assess environmental noise, there may be significant effects on the perception of the noise as a result of the influence on the spectrum at a receiver behind the barrier.

In the standard prediction schemes, complex traffic and railway noises are usually approximated by a line of coherent or incoherent monopoles. This type of source is assumed in several national and international standards, including the British CRTN³³ and CRN.³⁴ Improved analysis of continuous traffic noise can be achieved using a boundary element model based on the incoherent line source.¹⁹ Improved analysis of railway noise can also be performed if the incoherent line source model includes a dipole-type radiation component. A 15/85 combination of monopole/dipole radiation contributions is suggested in the Austrian model ÖAL-Richtlinie.³⁵ The effect of such a combination has been investigated by Morgan et al.³⁶ In computer simulations (e.g., Jonasson and Storeheier¹⁸), it is common to assume a distribution of static or moving-point sources on the road or railway. In this way it is possible to calculate the different attenuation spectra from sources with oblique rays over the barrier and at different distances. This could have a significant effect on the time-dependent indices that are used, that is, L_{eq} and L_{10} . In this way, the effects of position, emission spectrum, directivity of source, and speed can be analyzed. This is not possible with the line source approach.

The broadband efficiency of a noise barrier can be predicted for a given traffic noise spectrum, $L_0(f_n)$, using the following expression:

$$IL_B = 10 \log_{10} \left(\sum_{n=1}^N 10^{L_0(f_n)/10} \right) - 10 \log_{10} \left(\sum_{n=1}^N 10^{[L_0(f_n) - IL_0(f_n)]/10} \right) \quad (7)$$

where $IL_0(f_n)$ is the frequency-dependent insertion loss (dB) and N is the number of frequency bands, f_n ,

considered in the analysis. A representative traffic noise spectrum at the roadside is defined in EN 1793-3.⁴ The increase in the proportion of heavy vehicles tends to affect the broadband sound pressure level, whereas its effect on the shape of the noise spectrum is relatively small. On the other hand, for railway noise, the shape of the noise spectrum and its broadband sound pressure level can experience a 20-dB fluctuation depending upon the train type, speed, and the train position with respect to the noise barrier. The effect of the railway noise spectra (see, e.g., Morgan et al.³⁶) on the broadband efficiency of noise barriers has been studied by Horoshenkov et al.³⁷ While the efficiency of the plane screen is relatively unaffected by the spectral changes, the 4-dB to 7-dB variation of the noise efficiency of more exotic barrier designs, despite the higher insertion loss for the same height in terms of the A-weighted sound pressure level can be perceived as unacceptably high. Such fluctuations can be subjectively perceived to be more significant than the objectively measured gain of 1 dB to 2 dB in the average barrier performance.

6 INSERTION LOSS OF TREES AND SHIELDING CAUSED BY INTERVENING BUILDINGS

Often the insertion loss of tree belts alongside highways is considered relative to that over open grassland. An unfortunate consequence of the lower frequency ground effect observed in mature tree stands (see Chapter 5) is that the low-frequency destructive interference resulting from the relatively soft ground between the trees is associated with a constructive interference maximum at important frequencies (near 1 kHz) for traffic noise. Consequently, many narrow tree belts alongside roads do not offer much additional attenuation of traffic noise compared with the same distances over open grassland. A Danish study found relative attenuation of 3 dB in the A-weighted L_{eq} due to traffic noise for tree belts between 15 and 41 m wide.³⁸ Data obtained in the United Kingdom³⁹ indicates a maximum reduction of the A-weighted L_{10} due to traffic noise of 6 dB through 30 m of dense spruce compared with the same depth of grassland. This study found also that the effectiveness of the vegetation was greatest closest to the road. A relative reduction of 5 dB in the A-weighted L_{10} was found after 10 m of vegetation. For a narrow tree belt to be effective against traffic noise, it is important that (a) the ground effect is similar to that for grassland, (b) there is substantial reduction of coherence between ground-reflected and direct sound at frequencies of 1 kHz and above and (c) that the attenuation through scattering is significant.

If the belt is sufficiently wide, then the resulting greater extent of the ground effect dip can compensate for its low-frequency range. Through 100 m of red pine forest, Heisler et al.⁴⁰ have found 8-dB reduction in the A-weighted L_{eq} due to road traffic compared with open grassland. The edge of the forest was 10 m from the edge of the highway, and the trees occupied a gradual downward slope from the roadway extending about 325 m in each direction along the highway from the study site. Compared with open

grassland Huisman and Attenborough⁴¹ have predicted an extra attenuation of 10 dB for road traffic noise through 100 m of pine forest. They remarked also that whereas downward-refracting conditions lead to higher A-weighted sound pressure levels over grassland, the levels in woodland are comparatively unaffected. This suggests that extra attenuation obtained through use of trees should be relatively robust to changing meteorology.

Defrance et al.⁴² have compared results from both numerical calculations and outdoor measurements have been obtained for different meteorological situations. Their numerical method is based on a Green's fast parabolic equation (GFPE) method.²¹ A two-dimensional GFPE code has been developed⁴³ and adapted to road traffic noise situations⁴⁴ where road line sources are modeled as a series of equivalent point sources of height 0.5 m. The data showed a reduction in A-weighted L_{eq} due to the trees of 3 dB during downward-refracting conditions, 2 dB during homogeneous conditions, and 1 dB during upward-refracting conditions. The numerical predictions suggest that in downward-refracting conditions, the extra attenuation due to the forest is between 2 dB and 6 dB with the receiver at least 100 m away from the road. In upward-refracting conditions and at large distances, the adapted GFPE model predicts that the forest may increase the received A-weighted sound pressure levels somewhat, but this is of less importance since levels at such distances are relatively low anyway. In homogeneous conditions, it is predicted that sound propagation through the forest is affected only by the scattering by trunks and foliage.

Defrance et al.⁴² have concluded that a forest strip of at least 100 m wide appears to be a useful natural acoustical barrier. It should be noted that, in this study, both the data and numerical simulations were compared to A-weighted sound pressure levels without the trees present, that is, over ground from which the trees had simply been removed. This means that the ground effect both with and without trees would have been similar. This is rarely likely to be the case. ISO 9613-2¹ suggests a frequency-dependent foliage attenuation coefficient (see Fig. 8 in Chapter 5).

6.1 Buildings

For a single building, the double-diffraction calculations mentioned earlier could be used. For source or receiver situated in a built-up area, ISO 9613-2¹ proposes an empirical method for calculating the combined effects of screening and multiple reflections. The net attenuation A_{build} (<10 dB) is given by

$$\begin{aligned} A_{\text{build}} &= A_{\text{build},1} + A_{\text{build},2} \\ A_{\text{build},1} &= 0.1Bd_0 \text{ dB} \\ A_{\text{build},2} &= -10 \log[1 - (p/100)] \text{ dB} \end{aligned} \quad (8)$$

where B is the area density ratio of buildings (total plan area/total ground area) and d_0 is the length of the refracted path from source to receiver that passes through buildings. $A_{\text{build},2}$ is intended to be used only

where there are well-defined rows of buildings near to a road or railway. For such cases, p is the percentage of the length of facades relative to the total length of the road or railway. The area density ratio and the percentage of the length of facades can also account for the effects of arcades and intermittent building arrangement along a busy road. As with barrier attenuation, the attenuation due to buildings is to be included only when it is predicted to be greater than that due to ground effect. The ISO scheme offers also a frequency-dependent attenuation coefficient (dB/m) for propagation of industrial noise through buildings on an industrial site.

1 INTRODUCTION

Vibration is generated by road and rail traffic over a wide range of frequencies and amplitudes. Large-amplitude vibration can cause damage to track components, cracking of roadways, settlement of foundations, destabilization of embankments, and damage to nearby structures. But the focus of this chapter is on disturbance due to small-amplitude vibration. Vibration is perceptible at amplitudes several orders of magnitude below those generally required to cause damage to buildings. Regulations prescribe acceptable levels of vibration in the vicinity of new roads and railways and, in particular, near the tunnels of underground railway systems in cities. It is desirable to model accurately the generation and propagation of vibration because permission to build may only be granted if vibration can be shown to be within acceptable limits. There may also be restrictions applied if traffic patterns change, for instance, if nighttime freight trains are to be introduced on a line that normally carries only daytime passenger trains or if heavy bus traffic is to be increased on a residential road. This chapter addresses the issues confronting practicing engineers when asked to evaluate or mitigate ground vibration generated by road and rail traffic.

2 IMPACT OF GROUND-BORNE VIBRATION

Vibration generated by road vehicles and by trains can have significant environmental impact on nearby buildings. The general complexity of the problem is illustrated in Fig. 1. Inhabitants perceive vibration either directly as motion in floors and walls or indirectly as reradiated noise. A third and very significant source of disturbance is due to movement of household objects, especially mirrors, or by the rattling of window panes and glassware. In all these cases the problem of ground-borne vibration is important at frequencies typically up to 200 to 250 Hz.¹ Vibration at higher frequencies is generally attenuated rapidly with distance along the transmission path through the ground. Vibration can travel long distances from its

Figure 1 Sources of ground vibration and their transmission paths. (Courtesy of J. P. Talbot, Atkins Consultants, UK.)

source. For a ground with soft clay or silt, ground-borne vibration may produce annoyance to people in buildings more than 200 m away from tracks.²

Many studies and standards address the effect of vibration on buildings, their occupants, and on equipment. The British standard BS 6472:1992³ provides general guidance on human exposure to vibration in the frequency range 1 to 80 Hz. It provides curves for equal annoyance for humans plotted as root-mean-square acceleration versus frequency. The vibration dose value (VDV) is used as a vibration measure that takes into account the time history of the vibration (whether continuous or intermittent) for the day or the nighttime. The American National Standards Institute (ANSI) annoyance criteria due to vibration⁴ are described by the maximum weighted acceleration level and are given in Table 1.

Experimental work by Duarte and Filho⁵ shows that the sensitivity of people to a sinusoidal vibration decreases with frequency up to around 40 to 50 Hz. This is because the human head resonates around 20 to

Table 1 ANSI Criteria for Annoyance due to Ground-Borne Vibration

Building Use Category	Maximum Weighted Acceleration Level (dB re 10^{-6} g)
Hospital and critical areas	51
Residential (nighttime)	54
Residential (daytime)	57
Office	63
Factory	69

40 Hz, and hence it makes the person sensitive to even low amplitudes of vibration. Sensitivity increases again in the range between 50 and 100 Hz where the chest wall and ocular globe resonate. The work shows also that women are more sensitive to vibration than men.

Gordon⁶ develops generic vibration criteria (VC curves) for vibration-sensitive equipment. These curves are plotted in a similar way to the International Organization for Standardization (ISO) 2631-2:2003 guidelines for the effects of vibration on people in buildings.⁷ Vibration is expressed in terms of its root-mean-square velocity and is plotted as a one-third octave band. For a site to comply with a particular equipment category, the measured one-third octave band velocity must lie below the appropriate curve for the given category in Fig. 2.

Figure 2 Generic vibration criterion (VC) curves for vibration-sensitive equipment showing also the ISO guidelines for people in buildings. [Courtesy of the Institute of Environmental Sciences and Technology (IEST), Rolling Meadows, Illinois; www.iest.org.]

Due to the increasing public sensitivity to noise and vibration,⁸ railway companies must develop affordable vibration countermeasures and predictive tools to permit estimation of vibration levels in the early stages of planning for new railways. With increasing complaints about ground-borne vibration, many surveys are conducted to assess the vibration effect on buildings and their occupants and to help establish standards. In Nagoya, for example, the city authority conducts surveys about every 5 years to investigate the state of noise and vibration environment.⁹

A noise and vibration study by Fields¹⁰ based on interviews with people who live near railway tracks finds a generally high level of dissatisfaction within 25 m of the track. People interviewed in the range 25 to 150 m from the track report rapidly diminishing levels of complaint, and for distances beyond 150 m there is a uniform and low level of complaint. The study shows that many factors affect perception such as the duration of vibration, the time of day, background vibration levels, and various psychological factors such as whether the railway is visible.

It is generally believed that damage to buildings is associated with vibration, but this is unlikely as vibration generated by road traffic or railway trains rarely approaches the threshold of architectural damage.^{11,12} There are exceptions, and certain historic masonry structures are thought to have been damaged by traffic-induced vibration. Fear of damage to historic structures in Stockholm's medieval quarter Gamla Stan has been one of the obstacles to the building of a new track.¹³ The fear is arguably justified in cases where vibration has the potential to cause compaction and differential settlement of foundations of buildings close to roads or railways. This has been put forward as an explanation for the road-ward inclination of cathedrals and other ancient buildings.¹⁴

Turunen-Rise et al.¹⁵ and Klaboe et al.¹⁶ present a new Norwegian standard NS8176 for vibration in buildings from road and rail traffic. The standard introduces a single quantity to describe the vibration in buildings. This quantity is the statistical value of maximum velocity or acceleration, $v_{W,95}$ and $a_{W,95}$, respectively. These are calculated by recording the vibration for at least 15 passing trains or vehicles. For each record the third octave band frequency spectrum is calculated and weighted with weight values proportional to the human response at each band. Assuming a lognormal distribution of the root-mean-square values, $v_{W,95}$ and $a_{W,95}$ are calculated from the velocity and acceleration with a nonexceeding probability of 95%. In this standard vibration should be measured in a position and direction in the building that gives the highest vibration. A survey is conducted by questioning people who live in buildings where $v_{W,95}$ and $a_{W,95}$ were calculated using a prediction model developed by Madshus et al.² (see Section 5). According to the survey, it is found that there is no significant difference in reactions to vibration from different sources. Buildings are classified into four categories (A to D) according to the study, describing the building state in terms of vibration. In order to

provide a common answer format for sociovibrational studies and a better data exchange from future surveys to assess human perception of vibration in buildings, Klaboe et al.¹⁷ present a methodology to standardize carrying out a survey.

Research on ground-borne vibration, especially from underground railways, has recently gained prominence on account of the need to establish new underground tunnels in cities. There is also pressure to put high-speed intercity lines underground near residential areas. A particular feature of underground trains is the widespread notion that once underground the problem of noise goes away. But pure vibration in the absence of noise can be unnerving and more disturbing than vibration from visible and audible surface trains. Also of concern is that underground tunnels may pass near building foundations causing significant structural vibration. To address these issues a program of research entitled CONVURT (control of vibration from underground rail traffic) was established under the fifth framework of the European Union (EU) program for research, technological developments, and demonstration. The project had four main objectives: The first was to create validated innovative and quantitative modeling tools to enable accurate prediction of ground-borne vibration transmission into buildings.^{18,19} The second was to develop and evaluate new and cost-effective track and tunnel components to reduce ground-borne vibration and especially to develop devices capable of being retrofitted to existing track.²⁰ The third was to provide scientific input to allow the preparation of international standards. Finally, CONVURT has established guidelines of good practice for underground railway operation in order to maintain minimum vibration for the lifetime of operation.²¹

3 EXCITATION MECHANISMS

Vibration from road and rail vehicles derives from the inertia forces generated as vehicles pass over road and track irregularities. The nature of irregularities differs significantly between road and rail vehicles. For road vehicles much attention is given to potholes and speed cushions. A typical study is carried out by Watts²² to assess the vibration levels generated by vehicle crossing speed control cushions and road humps finds that these speed control measures can produce perceptible levels of vibration, but it is very unlikely to cause even minor damage to buildings. In general the resilience offered by pneumatic tires helps to reduce the generation of high dynamic forces and so reduce the level of traffic-induced vibration in the vicinity of roads. By contrast the dynamic forces generated by heavy steel wheels rolling on steel rails are high, and the rest of this section will address excitation mechanisms for rail vehicles.

Significant vibration in buildings near railway tracks and subway tunnels is attributed to moving trains. There are five main mechanisms for the generation of vibration. The first is a *quasi-static* mechanism, and it is significantly close to a track where the passage of individual axles can be distinguished. The passage of a vehicle can be represented by the passage of a

number of discrete concentrated static forces applied to the rails. As each force passes by, the observer experiences an oscillatory motion even though the applied force is constant. This may be visualized by imagining a child riding a bicycle over a large mattress; the vertical applied force is a constant, yet oscillatory motion is induced in objects resting on the mattress. The quasi-static effect contributes significantly to the low-frequency response in the range 0 to 20 Hz.^{1,23}

A second mechanism, known as *parametric excitation*, derives from the periodic support of rail by sleepers. The mechanism is similar to the quasi-static effect described above because vibration is generated when a constant wheel load moves along the rail at constant speed. The difference is that when it encounters variable rail support stiffness the resulting vertical motion of the wheel and axle cause dynamic forces to be applied to the rail. This is analogous to the same bicycle being influenced by individual springs in the mattress and the vertical applied force has an oscillatory component. Sleepers are uniformly spaced and excitation occurs at a frequency equal to the train velocity divided by the sleeper spacing (typically 25 Hz for low-speed trains and up to 150 Hz for high-speed trains). An investigation of this effect by Heckl et al.²⁴ gives results for the measured acceleration spectra near a railway track. It shows that peaks appear at some distinctive frequencies such as the sleeper-pass frequency, and also that the response can be large if the wheel track resonance coincides with one of the sleeper-pass harmonics.

A third mechanism occurs when wheels apply impulsive loading to the rail due to height differences at rail joints and crossings. This mechanism is becoming less important with the increasingly widespread use of continuously welded track, but the growth of surface unevenness is often more rapid in the vicinity of welds. Impulsive loading also occurs when the wheels have "flats" caused by skidding with locked brakes.

The fourth and generally most important source of vibration is that generated by rail and wheel unevenness or roughness. The unloaded rail profile is not smooth, and this is true even when the rail is new and has been recently installed. The reason is that the track and trackbed are never perfectly straight and flat. With time, ballast degrades and wheels and rails deteriorate so that rail roughness increases. Rail roughness contributes to vibration generation over a wide range of frequencies. Typical rail roughness has higher amplitudes for long wavelengths. An exception to this rule is that a major source of rail roughness is *corrugation* at wavelengths typically around 25 to 50 mm,²⁵ but for typical train speeds these short wavelengths generate vibration at frequencies well above 200 Hz. At low speeds (speed-restricted track and at the approaches to stations) dynamic forces due to corrugation are generally small in amplitude unless the track is badly corrugated. It is not generally necessary to consider corrugation when evaluating ground vibration from railways. Wheel roughness generally contributes to perceived roughness uniformly across the frequency range of interest to ground

Figure 3 Average measured downward and upward vertical displacement of a track with different train velocities. (Reproduced from Ref. 28, by permission.)

vibration.²⁶ There is a good summary of the various factors contributing to rail roughness by Hunt.²⁷

The fifth and final mechanism by which very large amplitudes of vibration can be generated occurs when train speeds approach or exceed either the speed of Rayleigh surface waves in the ground or the minimal phase velocity of bending waves in the track; see Fig. 3. In low-speed urban rail networks no attention need be given to this mechanism because the speed of trains is low compared with all critical wave propagation speeds. In recent years some attention has been given to this mechanism due to the increasing international trend toward higher speed trains; see, for example, Refs. 29 and 30. For the case of very soft soil, critical speed (often the Rayleigh wave speed) can be easily exceeded by modern trains. If the train velocity exceeds the Rayleigh wave speed, a ground vibration boom occurs. In a location near Ledsgard in Sweden the Rayleigh wave speed is around 45 m/s. An increase in train speed from about 38 to 50 m/s led to an increase of about 10 times in the generated ground vibration. If train speed increases further to the point where it reaches the minimal track phase velocity, larger deflections can occur with potential for train derailment. Vibration boom also occurs for underground trains if the speed reaches the velocity of shear waves in the ground.

There are other special sources of vibration excitation in addition to the five mentioned above. For instance, vibration is generated when a train approaches a bridge due to the change of trackbed geometry and stiffness.³¹ However, stiffness variation can be classified as a parametric excitation. There are also some avoidable sources of vibration, for instance, those due to static and dynamic out-of-balance of wheels, shafts, gearboxes, motors, and couplings aboard the train. Also there are disturbances that arise from tracking instability, cornering, flange contact, and gauge variation. These sources are generally of concern in older and poorly maintained track and are beyond the scope of this chapter.

4 MODES OF PROPAGATION

Dynamic forces generated at the road-wheel or rail-wheel interface propagate as vibration through

the ground and into buildings, causing annoyance to people. Vibration waves in the ground are superficially like sound waves in air except that in solids many different kinds of waves exist depending on the nature of the medium and its boundaries. Even in an isotropic elastic full space (the simplest of solid media being an elastic solid infinite in all directions), two kinds of waves can propagate, and these are called the body waves, moving spherically away from a localized point of excitation. The first is a dilatational wave, or a *pressure* wave (known as the P-wave). This is a wave similar to compressive waves in air where the particles within the medium oscillate parallel to the direction of propagation of the wavefront. The second is the equivoluminal wave, or the *shear* wave (known as the S-wave). This is a transverse wave where particle motion is perpendicular to the direction of travel of the wavefront. There is no equivalent to the S-wave in air because air possesses no stiffness in shear. The situation becomes more complicated when one considers that an elastic full space has no free surface and is therefore unsuited to modeling wave propagation in the ground. It is more common to use models based on an elastic half-space (see Fig. 4) where a third kind of wave appears, confined to the free surface. This is the *Rayleigh* wave, also known as the R-wave, and the motion of particles is elliptical in a plane perpendicular both to the free surface and to the wavefront. Rayleigh waves are superficially similar to surface waves in water, but, whereas water waves are controlled by the action of gravity or surface tension, the Rayleigh wave is controlled by the elastic properties of the solid. This leads to very different characteristics. For instance, the particle motion for Rayleigh waves is *retrograde* while for waves in water particle motion is *prograde*, which means that the particles orbit in opposite directions. Also unlike water waves the vertical component of particle motion in a solid is greater than the horizontal component. Both components decay exponentially with depth so that most of the energy associated with Rayleigh waves is confined near the surface to a depth roughly equal to the wavelength.³³ From a practical point of view the implication is that R-waves will not be attenuated by barriers (natural or man-made) that are small compared with the wavelength, but more on this later.

Pioneering work of Lamb³⁴ on the response of an isotropic elastic half space to different kinds of impulsive and harmonic loads forms the basis of all contemporary understanding of wave propagation in elastic half space. All three types of waves (P-, S-, and R-waves) are nondispersive. This means that their wave speeds are each independent of the excitation frequencies. In the ground, the P-wave speed is the highest, typically 400 to 800 m/s. The S-wave is somewhat slower than the P-wave and only slightly faster than the R-wave, typically 200 to 300 m/s. For the frequency range of interest, the distribution of energy between the three different kinds of waves are calculated by Miller and Pursey³⁵ for an elastic half space excited by a vertically oscillating rigid disk on the surface. Of the total input energy, 67% radiates as

Figure 4 Wave propagation in an elastic half space from a vertical surface load showing R-, S-, and P-waves. (Reproduced from Ref 32, by permission.)

R-waves, 26% as S-waves, and 7% P-waves. As P- and S-waves spread with hemispherical wavefronts in the ground, their decay rate is inversely proportional to the distance from the source. R-waves on the surface spread on a circular wavefront and with a decay rate inversely proportional to the square root of distance from the source. This reduction in amplitude with distance is called *geometric decay*. Material damping will also influence the rate at which energy decays with distance from the track, and to estimate this *material decay* it is necessary to use a model for damping.

For surface roads and railways and for buildings with reasonably shallow foundations, it is generally thought that the Rayleigh wave is chiefly responsible for vibration propagation. But this thinking is misguided in almost all situations due to the effects of layered media, wave reflections from bedrock, and the effects of building foundations. Some of these effects have analytical solutions. The Stoneley wave, for instance, appears at the discontinuous interface within an infinite solid formed by bonding two different half spaces. The Love wave (the fastest of all surface waves) moves within a surface layer bonded to a half space. The motion of particles is in a horizontal plane parallel to the free surface. Love waves can cause vibration to travel long distances from a source of disturbance. Practically speaking, real ground conditions are typified by continuous variation of soil properties with depth, and geological layers are generally inclined or discontinuous. Even if the dynamic loads applied to the track are purely vertical, the transfer of energy at the various tunnel-soil and soil-soil interfaces will cause all wave types to be excited. The depth of the water table is a further complicating and seasonally varying factor. Analytical solutions are unlikely to be of much use to practicing engineers, but an understanding of the underlying physics is useful for vibration propagation over long distances from the source. It

is useful to know that surface waves are of significance because they carry most of the energy and their geometric decay rate is low.

For propagation over long distances it is necessary to include a realistic model for damping. Modeling of damping is a matter of personal preference, and the most common approach is to use a material loss factor.³⁶ But given that many affected by vibration from railways live very close to the railway, it is not often necessary to be concerned about material decay. More important, however, are details of track components that may reduce the proportion of energy that enters the ground. For instance, energy that propagates along the rails may be dissipated before being transmitting into the ground. In tunnels the propagation process is more complicated due to interaction between the track, tunnel, and surrounding soil. It can readily be seen that vibration prediction from railways is not straightforward, but practicing engineers have evolved a number of methods for dealing with the various complications.

5 PREDICTION METHODS

There is increasing public sensitivity to noise and vibration, and transportation systems need to conform to increasingly stringent legislation. As a result engineers need accurate methods for predicting noise and vibration from road and rail systems. This section focuses on two prediction methods, while a good review of other methods can be found in the work of Leventhall¹¹ and Remington.¹²

The first is a method developed by Nelson and Saurenman.³⁷ It aims to estimate ground-borne noise and vibration from trains for a variety of building types, soil conditions, and track designs in the frequency range of 6.3 to 200 Hz in third octave bands. Design features such as resilient direct-fixation fasteners, floating slab track, resiliently supported sleepers,

Figure 5 Force densities for heavy rail transit vehicles. (Reproduced from Ref. 37 with permission.)

continuous welded rails, vehicle suspensions, and others are considered. The method predicts the level of noise and vibration at a building (existing or proposed) at some distance from an existing or proposed surface railway or subway. The force density at trackbed, calculated from field measurements, are provided as a set of curves for different types of trains and track systems; see Fig. 5. The unit of force density is force divided by the square root of train length. The force density represents an incoherent line source at the trackbed. The curves may not correspond exactly to the actual train track system under consideration, in which case adjustments are provided for variations including floating slab, ballast mat, and primary suspension stiffness. The next step in the method is to conduct a field test procedure to determine the response due to a line source by measuring a point-to-point transfer mobility (Green's function) from the railway to the ground surface. The transfer mobility can be calculated by striking the ground or the subway invert with a hammer and measuring the input force and the resulting vibration on the ground.

For a proposed subway, the hammer is struck at the bottom of a borehole drilled to the depth of the proposed tunnel. The transfer mobility of a point source is numerically integrated over the train length to calculate the response due to a line source representing the train. This adjusted force density and the calculated response due to a line source are used to determine the vibration at the location of the building foundation as if the building were not present. A *coupling loss correction* is then used to calculate the vibration at the building foundation for the frequency range of

interest. The coupling loss gives the third octave band curve of the actual foundation vibration relative to the level of incident ground surface vertical vibration that would exist in the absence of the building and its foundation. The vibration at the foundation is corrected by means of *floor-to-floor attenuation* and *floor resonance amplification* to obtain the third octave band of vibration at the floor under consideration. These predictions can also be used to estimate room noise levels.

A second—and very different—method developed by Madshus et al.² predicts the vibration velocity from railway trains using the following formula:

$$V = F_V F_R F_B \quad (1)$$

where $F_V = V_T F_S F_D$ is the basic vibration function. V_T is a train-type specific vibration level, defined as the vibration level on the ground at a reference distance of $D_0 = 15$ m from the center of the track, when a train of the specified category passes at reference speed of $S_0 = 70$ km/h on a standard track and embankment. $F_S = (S/S_0)^A$ is a speed factor, which accounts for the effect of the train speed S and A is the train speed exponent. $F_D = (D/D_0)^{-B}$ is a distance factor that accounts for the distance attenuation due to geometrical and hysteric damping. D is the distance from the center of the track to the receiver and B is the distance exponent. F_R is the track quality factor and F_B is the building amplification factor; it is used to transform the free-field ground vibration to floor vibration at the most unfavorable place.

Table 2 Typical Parameters for Prediction Method

Ground Conditions	Train Type	V_T (mm/s)	A	B
Soft clay	High speed	0.4–0.5	0.9–1.1	0.3–0.8
	Freight	0.7–0.8	0.9–1.1	0.3–0.4
Medium clay	High speed	0.1–0.15	0.9–1.1	0.9–1.0
	Freight	0.2–0.25	0.9–1.1	0.4–0.6

Source: From Ref. 2, reprinted by permission.

Equation (1) is used to predict one-third octave r.m.s values, with all factors being frequency dependent. Also a simplified version can be used at which all factors are frequency independent and directly related to the frequency-weighted root-mean-square (rms) velocity. The parameters of the model are computed based on a regression analysis. Typical parameters are given in Table 2.

There are other methods for predicting vibration from roads and railways. Examples are the prediction of loading and road response by Rudder³⁸ and the analytical-empirical ground vibration technique developed by Ungar and Bender.³⁹ These methods all have various merits. Individuals responsible for making vibration predictions will need to balance the need for accuracy against the resources (financial and computational) available. Some consultants will have access to an extensive database of vibration measurements from different sites, and their own experience will substantially enhance the usefulness of the predictive methods.

6 VIBRATION COUNTERMEASURES

Ballast in conventional railway track can act effectively to reduce vibration propagation. Generally, vibration countermeasures are required in confined spaces where ballast cannot be employed effectively. It is common to experience vibration problems where the rail is directly fixed to concrete or steel structures such as tunnels, bridges, and roadways. Vibration can also be controlled by careful attention to the detail of rail alignment, track foundation, widening of embankment (for surface railways), heavy tunnel structure, and increased tunnel depth.^{12,13,40} Vibration can also be reduced by controlling rail and wheel roughness. This is generally considered a maintenance issue rather than a vibration countermeasure. One exception is that roughness growth can be controlled by the implementation of lubrication, especially at curves. In general, though, rail and wheel grinding are required to keep rail roughness under control. Moreover, all vibration countermeasures will require maintenance and inspection for their continued effectiveness, and some countermeasures require less maintenance than others. It must always be born in mind that any alteration to the track may render it more susceptible to corrugation growth, and this may more than outweigh the benefit of vibration countermeasures.²⁵ This can work both ways: Too high a rail support stiffness may not only give poor isolation but may contribute to excessive rail corrugation and thus excessive vibration and noise.³⁷

Figure 6 Various rubber products used to reduce noise and vibration transmission from railways. (Courtesy of Getzner Werkstoffe GmbH, Bludenz, Austria.)

Vibration countermeasures fall into four categories. First, certain aspects of vehicle design will reduce dynamic force levels, for instance, by using low-stiffness vehicle suspension and a low unsprung mass (axle, axlebox, and wheel). Reducing the unsprung mass of a bogie can lead to a reduction of up to 10 to 15 dB in levels of ground-borne vibration.⁴⁰ Second, vibration can be isolated at the source by means of resiliently supported track (e.g., railpads and other resilient track support, resiliently mounted sleepers, ballast mat, embedded rail, and floating slab track) as illustrated in Fig. 6. Other in-track measures include reduced sleeper spacing and sleeper-mass redistribution.¹³ Third, vibration propagation can be interrupted, for example, by digging a trench in the vibration path between the source and the receiver. This is an area of extensive study,^{32,41} but two broad conclusions can be stated here. The performance of open trenches is better than that of concrete-filled trenches, and trench geometry has a clear effect on the isolation performance. Finally, vibration isolation can be achieved at the receiver by using rubber bearings or steel springs in the building foundations.

The most economic solution for vibration problems in old underground tunnels with directly fixed or ballasted track is likely to be resilient track support. The use of railpads does not raise the height of the rail significantly, which is an important consideration in small tunnels. A recent advance in resilient rail technology involves supporting the rail by the web and the underside of the head with large rubber wedges, leaving the foot of the rail suspended,²⁰ as shown in Fig. 7. This provides very low vertical dynamic stiffness while maintaining lateral stiffness required for vehicle and rail stability. The resilient bearing again has a low profile, and it can be installed and removed easily for maintenance. One possible disadvantage of using soft pads is that the level of noise radiated from the rail may be increased on account of the resiliently supported rail being less constrained by the base plates.¹³

Floating slab track is widely known as an effective measure of vibration isolation for underground tunnels. The track is mounted on a concrete slab that is fixed to the tunnel invert by means of rubber bearings or steel springs. The slab may be continuous or discrete (segmented). Continuous slab is cast in situ and segmented slab is constructed in discrete precast

Figure 7 Resilient support of a rail, the Vanguard system. (Courtesy of Pandrol Ltd, UK.)

sections. Discrete slab is convenient in many situations: It has the advantage that vibration propagation along the track is interrupted, but there is potential for maintenance problems if the slab segments are to move relative to each other, affecting track alignment. Continuous slab has the advantage of structural integrity, but it permits vibration to propagate along the tunnel, and this may lead to greater levels of radiation from the tunnel. Examples of floating slab tracks are the 1.5-m slab in Toronto, the 3.4-m Eisenmann track in Munich and Frankfurt, the 7-m slab in the New York City subway, and the British VIPACT continuous-slab system.

In circumstances where ballast is used, as is generally the case for surface trains and in some tunnels, the use of ballast mats can be very effective. A ballast mat is simply a mat of resilient material (usually rubber, but sometimes rockwool inserted underneath the ballast). It is analogous to the use of floating-slab track in underground tunnels. An example of the use of ballast mats within a tunnel can be found in the MBTA Boston in the United States. Ballast mats are also used to improve electrical isolation, water drainage, or to reduce pulverization of the ballast.¹² The mechanism by which ballast mats attenuate vibration is not well understood. One view is that the ballast mat acts as a spring supporting the mass of ballast leading to vibration isolation.⁴² An alternative view is that of the authors who believe that ballast mats are effective

on account of their ability to allow ballast to move under the application of axle loading. This prevents the ballast from “locking up.” The truth is, no doubt, a combination of these two effects.

In soft ground it may be necessary to improve the characteristics of the soil surrounding the track. Soil stabilization by means of injection grouting under and adjacent to the track is effective because it stiffens the soil structure, which reduces vibration propagation due the quasi-static effect.¹³ This can be particularly important for high-speed trains where trans-Rayleigh effects can cause large-amplitude vibration.

A common theme that runs through all attempts to assess the performance of vibration countermeasures is that trends are difficult to identify. It is found, for instance, that measures effective for one site are less effective for another and that the effectiveness of in-track countermeasures is sometimes found to reduce with distance from the track. It is clear that detailed modeling is required to make sense of these observations and that accurate models can be used to drive the development of new countermeasures.

7 MODELING

The strategy for modeling ground vibration from road traffic differs from that for rail traffic mainly because of the difference in excitation mechanisms. For road vehicles the pavement can be considered to be rigid, and the vehicle suspension is responsible for controlling the dynamic forces generated in response to road roughness. This permits a decoupling of the excitation mechanism from the wave propagation mechanism, which simplifies modeling. However, for rail vehicles the unsprung mass of wheel and axle combine with the mass of that part of the rail within the deflection bowl to move in response to rail roughness. Decoupling is no longer possible. Nevertheless, the propagation mechanisms are largely common to both problems, and an understanding of wave propagation and modeling of the response of a half space under different kinds of loading is essential before embarking on any detailed modeling. Much of the fundamental work was discussed in Section 4, but there are some further fundamental issues that require discussion. These include: (1) the effects of moving loads, (2) random vibration theory, (3) track modeling, (4) tunnel modeling, and (5) ground modeling. For any realistic model of traffic-induced vibration, all these effects will need to be considered. Most can only be addressed through extensive use of mathematical techniques (Fourier, wavelet, and Floquet transforms) and through the use of computational techniques such as the finite element and boundary element methods (FEM–BEM). It is not possible here to do more than to identify the various techniques.

Early models for computing vibration generated from moving loads used a solution of moving constant force on elastic half space. More advanced developments were made possible by including the inertial effect of vehicles. Fryba⁴³ discusses lucidly several aspects of vibration of solids and structures under moving loads. Moving loads can be classified in three

ways depending on whether the speed is less than, equal to, or greater than the lowest wave speed in the structure—that is, the critical speed. Above the critical speed, waves analogous to shock waves are generated, producing large amplitudes in the structure. These large amplitudes are only to be expected in soft ground or on flexible structures; most readers need not concern themselves with the critical speed.

A theoretical analysis of the transmission of road-vehicle-induced vibration through the ground by Hunt⁴⁴ considers vibration as a Gaussian-distributed random process. Vehicles are modeled as single-axle two degrees of freedom. Power spectral expressions are calculated for the vertical ground acceleration away from a long straight road. Only a half-space model is used (i.e., no layering), and approximate methods are used to account for the effect of the bending stiffness of the road surface. A series of measurements is presented to validate the model, and a parametric survey demonstrates the sensitivity of traffic-induced ground vibration levels to ground properties, vehicle speed, traffic intensity, road roughness, and vehicle characteristics. This methodology is extended by Hunt⁴⁵ for the calculation of building vibration generated by railways using theory of random vibration and models of infinite length for both building and track.

The Winkler beam⁴⁶ (or *beam on elastic foundation*) is used extensively to model railway tracks. Discrete supports of rails can be assumed as an elastic foundation of Winkler type. The benefit of using Winkler beam theory to model railway track is that it is relatively easily coupled to models of the ground. But while Winkler beam methods are within the computational abilities of many engineers, they do not enable the beneficial effects of track resilience to be computed with any accuracy. It is not unusual for insertion loss performance figures of 30 dB or better to be quoted based on Winkler theory, but it is generally found that such performance cannot be achieved in practice. At any reasonable distance from the track, it is unrealistic to expect insertion loss of greater than 15 dB from even the best of vibration countermeasures.

A theoretical model for both the generation and propagation of vibration from freight trains is presented by Jones and Block.¹ The model accounts for both the rail roughness and the quasi-static effect of moving axles. The input to the model is taken from measurements by using a track recording coach. The predicted vibration agrees well with the measured vibration in the frequency range of 5 to 30 Hz. It is found that heavy freight trains emit ground vibration with predominant frequency component in the range of 4 to 30 Hz.

Sheng et al.^{23,47–49} present a fully three-dimensional model of a railway track coupled to a multilayered half space. Both of the rails are modeled as a single Euler–Bernoulli beam, and railpads are modeled as a continuous resilient layer. Sleepers are modeled as a continuous beam with no bending stiffness, and ballast is modeled as a continuous layer of a linear spring with a consistent mass approximation. The results show a good agreement with measurements taken at three different

sites and demonstrate the dominance of the quasi-static effect near the track at low frequencies. The model is used to investigate the effect of track properties on ground-borne vibration.

Krylov⁵⁰ presents a model to investigate the effect of high-speed trains on ground vibration. The important feature of the model is that it accounts for sleeper spacing and the quasi-static forces of the moving train. This model is used by Krylov et al.²⁹ to predict the vibration generated by the French TGV and Eurostar high-speed trains along tracks built on soft soils. Degrande and Lombaert⁵¹ use the Betti–Rayleigh dynamic reciprocity theorem to increase the efficiency of Krylov's model. Degrande and Schillemans⁵¹ compare the results from this model with free-field vibration measurements during the passage of a Thalys high-speed train at various speeds. The model gives good predictions at low frequencies where the quasi-static response dominates and at high frequencies where sleeper-passing response dominates. At the mid-frequency range where other mechanisms, for example, rail roughness are important, the model underestimates the response. Another theoretical and experimental study on vibration from high-speed trains is presented by Kaynia et al.²⁸ where a good match is shown between the predicted and measured results.

A three-dimensional semianalytical model for a floating-slab track in a deep underground tunnel is presented by Hunt.⁵³ The model consists of Euler–Bernoulli beams to account for the rails and the track slab. The slab is coupled to the *pipe-in-pipe model*, which consists of a thin shell (the inner pipe) representing a tunnel, embedded within an infinite continuum with a cylindrical cavity (the outer pipe) representing the surrounding soil. Coupling is performed in the wavenumber–frequency domain. Three-dimensional numerical models are developed by some researchers to model vibration from underground railways. The main disadvantage of these models is that they are computationally expensive. Powerful numerical models are developed under CONVURT, where a coupled FEM–BEM is used. The FEM is used to model tunnel walls while the BEM is used to model the surrounding soil. Taking account of periodicity in the tunnel direction using Floquet transformation makes a significant improvement in the running time.⁵⁴

Coupled FEM/BEM are also used to model road-traffic-induced vibration. An example is the work of Pyl et al.,⁵⁵ which incorporates a moving source and accounts for soil–structure interaction. A two-dimensional vehicle model is used on longitudinal road roughness to account for the source, and the input is calculated by assuming the vehicle response to be uncoupled from the road–soil response. The finite element method is used to model a building where the vibration is predicted, and the boundary element method is used to model the ground. An example of the power of coupled FEM/BEM methods is illustrated in Fig. 8.

A different numerical method is used by Sheng et al.⁵⁶ This method is the *discrete wavenumber*

Figure 8 Example of boundary element modeling. Vibration of a building near a Metro tunnel in Paris. (Courtesy of D. Clouteau, École Centrale, Paris.)

fictitious force method and is used to model an underground tunnel embedded in a half space. The method depends on writing the boundary integral equations of only the displacement Green's function. This is an advantage over the BEM as the traction Green's function is not required. The finite difference method⁵⁷ may also be used to model the traffic-induced and rail-induced ground vibration. Its advantage is thought to be that the computational code is much simpler than conventional numerical methods such as BEM and FEM.

The methods described here are of limited use in practice for four reasons: First, they require substantial computational resources in addition to a working knowledge of some fairly high powered analytical tools. Second, a large quantity of input data is required for the models, and this may not be readily available. In particular, the variation of soil properties with depth is unlikely to be known to great accuracy, and the quality of predictions made can only be as good as the quality of the input data. Third, few of these models are validated over a wide range of different track and ground conditions. It may be more sensible to use an older and simpler predictive method that has stood the test of time. Finally, no models presently available take into account the nonlinearities of track elements and of soils. These are likely to be significant if accurate predictions are to be made.

8 CONCLUSION

There is no simple answer for the computation of vibration generated by road or rail traffic. Simple models do not work with sufficient accuracy and elaborate models are computationally expensive. Empirical models are valid only in certain simplified circumstances and experimental measurement of vibration is only really useful when there is the option of trying out various different methods. It is the view of the authors that substantial advances in vibration reduction will only occur when the computational tools are widely

available and in the hands of the engineers responsible for road, track, and tunnel design.

CHAPTER 124

BASE ISOLATION OF BUILDINGS FOR CONTROL OF GROUND-BORNE VIBRATION

James P. Talbot
Atkins Consultants
Derby, United Kingdom

1 INTRODUCTION

There are many sources of ground-borne vibration in our cities. Some, such as the piling of a new building foundation, are short lived and relatively few people are affected. Others, such as the passage of vehicles on roads and railways, are a more permanent feature of the urban environment. These sources may cause daily disturbance to building occupants, with significant social and economic consequences.

Base isolation involves inserting isolation bearings between a building and its foundation in order to reduce internal levels of perceptible vibration and reradiated noise. Either rubber bearings or steel springs may be used. Since the introduction of base isolation techniques in the 1960s, they have become well established as one of the most effective means of controlling ground-borne vibration. These bearings are now used in residential buildings, office towers, concert halls, cinemas, and hospitals.

2 SOURCES OF GROUND-BORNE VIBRATION AND THEIR CONTROL

The dominant sources of urban ground-borne vibration fall into three categories: construction activity, roads, and railways. With the possible exception of certain construction activities, vibration levels are unlikely to cause damage to buildings. Typical levels due to road and rail traffic lie in the range from 0.1 to 1.0 mm/s and peak in the frequency range from 10 to 100 Hz. Such levels are significantly below those at which even light damage, such as the cracking of plaster, may be expected. Nevertheless, the daily disturbance caused to building occupants and the disruption caused in specialist buildings, such as hospitals and research facilities, can have significant social and economic consequences.

There are many examples of construction activity that generate ground-borne vibration: blasting, tunnelling, piling, and vibratory compaction can all cause disturbance in nearby buildings. These sources are usually short lived and relatively few people are affected. They are best controlled by careful design and management of the activities themselves.

In contrast, road and rail vehicles can cause disturbance to large numbers of people many times a day. In particular, railways carry heavy vehicles at high speed, often passing within a few metres of buildings and their foundations. They are generally regarded as the most significant source of ground-borne vibration. Railways may make use of vibration

control measures at source, and a variety of isolation systems are available for incorporation within the track. Further details may be found in Chapter 123.

Control at source is not always possible. For example, where new buildings are constructed near existing railways, it may be difficult and expensive to take retrospective measures with either the vehicles or the track. In such cases measures are usually restricted to the buildings themselves. A variety of straightforward cost-effective measures exist that may be sufficient to control low levels of ground-borne vibration. Damping treatments may be incorporated into the building structure, floating floors installed, or local stiffening undertaken to control structural resonances. However, in certain cases the level of ground-borne vibration may be considered large enough to justify the base isolation of a building. Figure 1 illustrates a typical example. In this case a multistory office building is isolated on spring bearings located in the basement car park.

3 DECISION TO BASE ISOLATE AND ITS IMPLICATIONS

The level of vibration within a building that is considered acceptable is dependent upon many factors, such as the duration and nature of the vibration, the type of building, the activities of its occupants, and what the occupants feel, hear, and see. More subjective factors may also be involved, such as what the occupants expect to experience, concerns over structural damage, and whether they believe anything could or would be done to improve the situation, such as reducing the vibration or awarding compensation, if they were to complain.

A number of standards aim to provide guidance on the acceptable levels of perceptible vibration in buildings, such as the British standard (BS) 6472¹ and the International Organization for Standardization (ISO) 2631-2.² Table 1 reproduces levels given in both these standards at which adverse reactions may be expected from people living and working in buildings. The levels are expressed as vibration dose values, a measure deemed appropriate for assessing transient vibration, such as that from a passing train. Further information may be found in Chapter 30. In some buildings, such as hospitals and research facilities, the acceptable level is determined by the nature of the equipment they contain.^{3,4}

Audible noise radiated from the vibrating structure of a building can also cause disturbance. In the case

Figure 1 Typical base-isolated building in the form of a multistory office. (Courtesy of GERB Schwingungsisolierungen GmbH & Co, Germany.) The entire building is isolated from its foundation by spring bearings located in the basement.

Table 1 Vibration Dose Values ($\text{m/s}^{1.75}$) Suggested in BS 6472 and ISO 2631-2 at Which Adverse Reactions May Be Expected from Building Occupants

Place	Low Probability of Adverse Comment	Adverse Comment Possible	Adverse Comment Probable
Critical working areas	0.1	0.2	0.4
Residential	0.2–0.4	0.4–0.8	0.8–1.6
Office	0.4	0.8	1.6
Workshops	0.8	1.6	3.2

of railway vibration, this *reradiated noise* manifests as a low-frequency rumble, which may be audible even when the vibration itself cannot be felt. The peak frequency component of the noise does not necessarily coincide with that of the vibration because it depends on the radiation efficiency of the structure concerned. It is typically most noticeable in the frequency range from 50 to 125 Hz. No standards currently exist specifically concerning internal reradiated noise, although

various guidelines exist, such as those produced by the American Federal Transit Administration (FTA).⁵

In practice, the decision on whether or not to base isolate a building is usually based on a series of vibration measurements. These are made either at the site in question, prior to any construction work, or on a similar building to the one being designed. The data collected may then be analyzed in light of previous experience and with the aid of the appropriate standards and theoretical models.

3.1 Practical Implications

There are practical design implications, not normally associated with a typical building project, that must be addressed once the requirement for base isolation has been established. A major implication is the reduction in structural stiffness and overall stability due to mounting the building on isolation bearings. Some tall buildings are constructed of floor slabs supported on columns and derive their stiffness from a service tower or lift shaft. Once such a building is mounted on bearings, the stiffness of the structure is often no longer adequate and additional stiffening is required. Additional horizontal stability may need to be provided by sets of horizontal bearings.

Additional consideration must be given to settlement of the building on its bearings, either during construction or subsequently through creep in the bearings, fire proofing of the bearings, and designing fail-safe measures for the unlikely event of a collapsed bearing. Care must also be taken not to “bridge” the isolation by, for example, staircases, building services, construction debris, or acoustical coupling. Suppliers of base isolation bearings are usually able to advise on these matters.

4 GENERIC DESIGN PRINCIPLES

The underlying principles of base isolation are similar to those used to protect buildings against earthquakes, although the practical implementation of isolation against ground-borne vibration differs due to the lower vibration amplitudes and the presence of higher frequencies. Seismic isolation of buildings is the subject of Chapter 117.

This chapter is concerned with *base*-isolated buildings and, usually, design considerations do indeed require the bearings to be located at the base of the building, such as on the pile caps or at basement level. In principle, it is possible to locate the bearings higher up the structure and isolate only the upper floors. However, this should be done with care as amplification of the ground vibration due to resonances of the unisolated structure below the bearings may reduce their performance.

No standards currently exist specifically governing the design of base-isolated buildings. In practice, design strategies are based on past experience and the requirements of the particular project. It is common practice to consider only vertical motion of the building: The horizontal component of ground motion is generally neglected on the assumption that the building’s inherent flexibility in this direction provides

sufficient isolation. However, there is theoretical evidence to suggest that this may not always be the case.⁶ It is now generally recognized that the structural elements at the base of a building exhibit a combination of vertical, horizontal, and rotational motion. It is, therefore, recommended that all three primary modes of deformation of an isolation bearing are accounted for during design, as illustrated in Fig. 2.

As originally proposed by Waller,⁷ on the basis of vertical motion being dominant, base isolation systems are principally defined in terms of their *isolation frequency*. This is the resonance frequency of the building on its bearings assuming it behaves as a rigid mass on a spring. Note that effective isolation does not begin until frequencies somewhat higher than the isolation frequency, as discussed later. The isolation frequency must, therefore, lie sufficiently below the frequency range of the ground-borne vibration in order to avoid excessive low-frequency motion of the building.

Typical isolation frequencies lie in the range from 5 to 15 Hz, and a lower isolation frequency generally gives rise to more effective isolation. However, they should be quoted with care, primarily due to the limitations of the single-degree-of-freedom model. For example, the rocking modes of a building are likely to occur at frequencies significantly different from the vertical "bounce" frequency.

Isolation frequencies should be based on the dynamic stiffness of the bearings, which can depend on several factors, such as excitation frequency and static load. Allowance should also be made for secondary stiffnesses, such as those associated with seals between adjacent structures, and the mass should be based on the "unfactored" dead load of the building, including allowances for furniture, occupants, and equipment.

The level of inherent damping offered by bearings is also often quoted as an important design parameter. Base isolation relies on vibration isolation rather than energy dissipation, the basic requirement being a low dynamic stiffness. For maximum isolation, therefore, current designs are based on the inherent damping being as low as possible, provided that sufficient damping is present to control any internal resonances of the bearings themselves. It is generally true that sufficient damping is provided by structural elements within a building, and by vibration re-radiated into the foundation, so that the bearings themselves do not need to provide damping.

Figure 2 Three primary modes of deformation associated with an isolation bearing: (a) vertical compression, (b) horizontal shear, and (c) rotation.

4.1 Rubber Bearings and Steel Springs for Base Isolation

Despite many different types of isolation bearing having been tried in the past, the choice for modern buildings essentially lies between laminated rubber bearings and steel helical springs,^{8,9} as illustrated in Fig. 3. Rubber bearings are available in two different types: either carbon-loaded natural rubber, reinforced and stiffened by laminating with steel plates, or synthetic rubber made more flexible by loading with cork particles and reinforced with layers of woven cloth. Spring bearings are supplied in units containing several steel helical springs. These may include additional damping elements to limit vibration transmission at the internal resonance frequencies of the bearing. Examples include the incorporation of "noise-stop pads," in the form of rubber pads inserted above or below the springs, or the use of auxiliary viscous dampers.

Some bearings are available precompressed between two steel plates, typically up to 80% of the

Figure 3 Base isolation bearings are available as either laminated rubber bearings or steel helical springs. (Courtesy of CDM, Belgium and GERB Schwingungsisolierungen GmbH & Co, Germany.)

expected static load. This does not influence the isolation performance, but it does limit the static deflection of the building during construction. It also enables postconstruction adjustment of the bearings, should differential settlement be detected, for example.

In summary, when selecting a particular bearing design, the following primary characteristics should be considered.

- *Isolation frequency* This is the parameter commonly used for defining the vertical dynamic stiffness of the bearings for a particular application.
- *Horizontal and rotational stiffness* As well as influencing the isolation performance, these influence the horizontal stability of the building.
- *Dynamic/static stiffness ratio* The dynamic stiffness determines the isolation performance while the static stiffness controls the level of settlement during construction, or the level of precompression required to limit this. Dynamic stiffness is more difficult to measure than static stiffness and data may not be available for some materials.
- *Inherent damping* For a low dynamic stiffness this should be as low as possible, provided that sufficient damping is present to control any internal resonances of the bearings.

All of the above characteristics influence isolation performance to some extent and should be considered during design. The remainder of this chapter discusses the measurement and prediction of isolation performance in order to aid this process.

5 ISOLATION PERFORMANCE

No standard measures exist for assessing base isolation performance, although three categories of measure are encountered in practice: “green-field” site predictions, predictions given a particular source, and insertion gain. The first two are measures of *absolute* performance while the third is a measure of *insertion* performance.

5.1 Absolute Performance

The future occupants of a new building are interested in the absolute performance of the isolation, that is, what they will experience in the completed building. Engineers may satisfy this by predicting vibration levels within the isolated building given vibration data measured on the green-field site prior to any construction work. This approach often forms the basis of a decision on whether or not base isolation is necessary. Green-field site predictions require knowledge of the effects of the building and its foundation on the ground vibration field, as well as an understanding of the dynamic behavior of the building itself.

Alternatively, predictions of the vibration levels due to a particular source may be required. In this case, particular care must be taken as a detailed understanding of the entire vibration transmission path is required.

5.2 Insertion Performance

The client who pays for the additional cost of base isolation is interested in the insertion performance, that is, the benefit of inserting isolation bearings beneath a building. It is also of interest to the engineer who wishes to evaluate alternative types of bearing.

It is worth stressing that performance generally cannot be characterized by making in situ vibration measurements above and below bearings. Lower vibration levels above a bearing should not be regarded as indicative of isolation performance because such measurements concentrate on the forced response of only a small part of a complex structure. In addition, any difference in vibration levels across a bearing may be exaggerated by the existence of higher levels below the bearing than would otherwise exist if the building was unisolated. This is due to the decoupling of the building from its foundation and the consequent reduction in constraint at the base of the building.

In principle, if the building already exists, internal vibration measurements may be made before and after installation of the bearings. However, this can be difficult and expensive to achieve in practice, and, if attempted, an effective measurement program requires careful thought concerning the measurement locations, the quantity to be measured, and in what direction. A comprehensive evaluation of performance should account for the necessary structural changes associated with base isolation—the structure and foundation of an isolated building may be quite different from the unisolated design.

Given the difficulties associated with measurements, predictions of performance are essential in guiding design. A common measure of insertion performance is *insertion gain* (IG). This is the ratio, usually expressed in decibels, of the building response with bearings in position to that with no bearings at all:

$$IG = 20 \log_{10} \left(\frac{x_{\text{isol}}}{x_{\text{unisol}}} \right) \quad (1)$$

where x_{isol} and x_{unisol} are the responses of the building in the isolated and unisolated condition, respectively. Either the displacement, velocity, or acceleration response may be used because it is assumed that the behavior of the building is linear. Note that the reciprocal of IG is *insertion loss*, which, although a commonly used term, may be confusing because it defines a *loss* as a positive quantity.

Insertion gain is based on vibration amplitudes, and it is of limited use as a single measure of isolation performance due to the fact that it only accounts for vibration occurring in one direction and varies with position in a building. A more useful measure is *power flow insertion gain* (PFIG).⁶ The principal behind PFIG is that the mean vibrational energy entering a building drives all internal noise and vibration, assuming there are no internal sources of either. A reduction in PFIG is therefore guaranteed to reduce

the average noise and vibration levels in a building:

$$\text{PFIG} = 10 \log_{10} \left(\frac{\bar{P}_{\text{isol}}}{\bar{P}_{\text{unisol}}} \right) \quad (2)$$

where \bar{P}_{isol} and \bar{P}_{unisol} are the total mean power flows entering a building in the isolated and unisolated cases, respectively.

Power flow IG has clear advantages over performance measures based on vibration amplitudes because it accounts for multidirectional vibration at multiple inputs and is insensitive to the spatial distribution of vibration levels within a building. It is useful in design because the variation in performance with frequency, for a particular set of design parameters, may be represented by a single curve. For the case of a single-input single-output system, PFIG can be shown to be directly equivalent to IG.

6 MODELING BASE-ISOLATED BUILDINGS

6.1 Single-Degree-of-Freedom Model

The single-degree-of-freedom (SDOF) model serves as a useful introduction to the principles behind base isolation. Figure 4 illustrates how a building may be represented as a rigid mass supported on a spring-damper element to represent the isolation bearings—in this example a viscous dashpot is used to model damping. Ground-borne vibration is represented by an imposed displacement amplitude X at the base of the spring-damper. The resulting motion of the building is described by the displacement amplitude of the mass Y .

The precise expression describing the variation in the ratio Y/X with frequency depends on the nature of the damping element,¹⁰ but the essential features are the same in all cases: (1) the bearings act to amplify low-frequency vibration, and this is greatest at the

isolation frequency; (2) the bearings are only effective for frequencies greater than $\sqrt{2}$ times the isolation frequency, above which the isolation improves with frequency; and (3) damping acts to limit the resonance amplitude but reduces the isolation performance.

These features of the SDOF model suggest some guiding design principles, but the model is too simplistic for making any useful predictions of isolation performance. For this, a more comprehensive representation of a building, its foundation, and the vibration source is required.

6.2 Modeling for the Prediction of Isolation Performance

Predictions of isolation performance may be obtained from empirical models, based on a database of measurements made on existing buildings. These can provide useful, as well as reasonably rapid, estimates of performance provided the database is sufficiently comprehensive to cover the possible combinations of source, transmission path, type of building, and the like. The disadvantage of empirical models is that they treat each part of the vibration transmission path separately, and the various factors and transfer functions are assumed to be independent. This does not represent the physical situation and cannot account for coupling between various parts of the system, such as that due to interaction between the building and its foundation.

An alternative is to use theoretical models based on physical laws. These are particularly useful during design as they may be tailored to the particular project and, in principle, include as much physical detail as necessary. The required level of detail depends on the particular application, but any model should include a representation of the building, its foundation, and the vibration source. Models may be formulated in either the time or frequency domains. The former is often

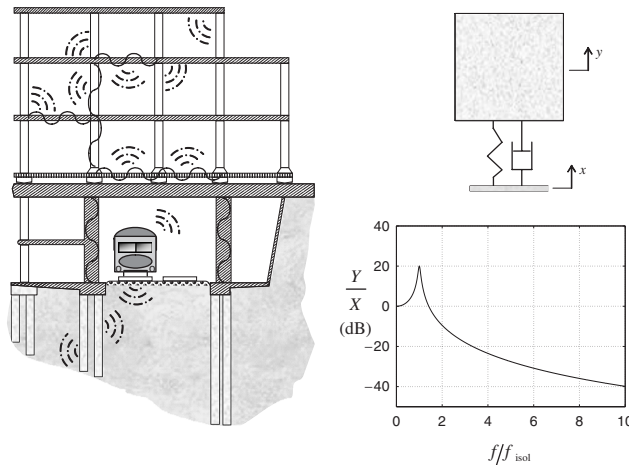

Figure 4 principles of base isolation may be introduced by the single-degree-of-freedom model in which a building is represented as a rigid mass supported on a spring-damper element to represent the isolation bearings.

used for seismic analysis where peak vibration levels due to a transient, and often nonlinear, event are of interest. When dealing with ground-borne vibration, the response, particularly that due to railways, is of sufficient duration that the frequency domain is the most appropriate. The problem may also be treated as linear given the low strain amplitudes involved. In this case, irrespective of the particular methods employed, the modeling process may be broken down into the following steps. The entire process must be followed for each frequency of interest.

1. Calculate the foundation's frequency-response function (FRF) matrix \mathbf{H}_f^{11} . This relates vectors \mathbf{u}_{bf} and \mathbf{f}_{bf} containing the displacement and force amplitudes at various locations, or *nodes*, on the building-foundation interface.
2. Assemble a vector \mathbf{u}_{bf0} containing the displacement amplitudes at nodes on the building-foundation interface in the absence of the building. This represents the input to the final model. By considering equilibrium of forces and compatibility of displacements, the displacements of the building-foundation interface in the presence of the building may be obtained by superposition:

$$\mathbf{u}_{bf} = \mathbf{H}_f^{11} \mathbf{f}_{bf} + \mathbf{u}_{bf0} \quad (3)$$

3. Calculate the building's FRF matrix \mathbf{H}_b . This relates displacement and force amplitudes at nodes throughout the building model. Because the forces acting on the building are equal and opposite to those acting on the foundation, and no other external forces are assumed to act on the building, \mathbf{H}_b may be partitioned according to whether nodes lie on the building-foundation interface or elsewhere in the building:

$$\begin{bmatrix} \mathbf{u}_{bf} \\ \mathbf{u}_b \end{bmatrix} = \begin{bmatrix} \mathbf{H}_b^{11} & \mathbf{H}_b^{12} \\ \mathbf{H}_b^{21} & \mathbf{H}_b^{22} \end{bmatrix} \begin{bmatrix} -\mathbf{f}_{bf} \\ \mathbf{0} \end{bmatrix} \quad (4)$$

where \mathbf{u}_b contains displacements at nodes other than those located on the building-foundation interface. Eliminating \mathbf{f}_{bf} from Eqs. (3) and (4) gives

$$\mathbf{u}_{bf} = [\mathbf{I} + \mathbf{H}_f^{11} [\mathbf{H}_b^{11}]^{-1}]^{-1} \mathbf{u}_{bf0} \quad (5)$$

The interface displacements in the presence of the building may, therefore, be calculated from those in its absence.

4. The final stage is to calculate the building-foundation interface forces using Eq. (4):

$$\mathbf{f}_{bf} = -[\mathbf{H}_b^{11}]^{-1} \mathbf{u}_{bf} \quad (6)$$

These may then be used to calculate the remaining building displacements:

$$\mathbf{u}_b = -\mathbf{H}_b^{21} \mathbf{f}_{bf} \quad (7)$$

Depending on the intended use of the model, a variety of methods may be used to implement each of the above steps. Some of the most common methods are described below.

6.3 The Building Model

Any building model should represent, to some degree, the mass, stiffness, and damping of the building's primary structure. Accounting only for the mass—as in the SDOF model—is insufficient because the vibration modes of a building can result in a significant reduction in base isolation performance.¹¹ Comprehensive models should account for the essential dynamic behavior of a building's floors and columns, and the dynamic coupling between them.

The finite element method (FEM)¹² is now the most widely used numerical technique for engineering analysis and is a natural choice for modeling vibration of buildings. It has the advantage of being readily available commercially and may provide the most efficient means of generating comprehensive three-dimensional models. However, the FEM usually employs modal analysis and care must therefore be taken to ensure an adequate number of elements are used for the required accuracy over the frequency range of interest.

An alternative to the FEM is the dynamic stiffness method.¹³ This is computationally efficient and particularly suited to producing two-dimensional portal frame models, although it may also be extended to three dimensions. The method is based on the analytical solutions of Euler beam theory and that describing an elastic bar. It is therefore exact within the limitations of the theory.

Statistical energy analysis (SEA) is another numerical technique for modeling noise and vibration transmission through structures. This includes buildings when the frequencies of interest lie within the audio range.¹⁴ The problem with applying SEA to ground-borne vibration is that the frequencies of interest include only a few hertz, when the fundamental assumption of SEA—that of high modal density—does not apply. In addition, SEA elements for describing the interface between a foundation and the ground are not generally available in SEA codes. Despite its computational efficiency, SEA is therefore not recommended for modeling base-isolated buildings.

6.4 The Foundation Model

A building and its foundation are intimately coupled, and a significant degree of dynamic interaction occurs between them. The foundation and surrounding ground not only provide the transmission path from the vibration source, but they also act as a sink of vibration propagating in the building. The foundation model is

therefore an essential component of any model aimed at predicting isolation performance.

When modeling the semiinfinite extent of the ground, domain methods, such as the FEM or finite difference method,¹⁵ suffer from a fundamental problem. The element mesh should extend toward infinity but in practice must be curtailed at a certain distance. The resulting artificial boundary leads to spurious wave reflections that can distort the solution. A simple solution to this problem is to use models large enough that insufficient wave energy reaches the model boundary. This approach is usually impractical given the computational requirements of the models. A solution available in some commercial FEM codes is to use non-reflecting boundaries or so-called infinite elements.¹⁶ These help account for wave radiation to infinity but only approximately due to the difficulty of accounting for the different wave types.

One technique ideally suited to the modeling of ground-borne vibration is the boundary element method (BEM).¹⁷ In contrast to the FEM, the BEM requires the discretization of only the domain boundaries, rather than the full domain. The governing equations are automatically satisfied, and the radiation of waves to infinity is automatically accounted for. As with the FEM, if necessary, the BEM enables the representation of different soil strata and inhomogeneous soils through the use of multiple BEM domains and appropriate fundamental solutions.

6.5 Note on Damping

Structural damping is the least well-understood aspect of structural dynamics and remains the subject of current research. In the frequency domain, material damping may be conveniently modeled by assuming viscoelastic behavior and replacing the standard elastic constants with suitable complex values.¹⁸ Thus, for example, Young's modulus E becomes $E(1 + i\eta_E)$. In practice, damping is often found to be approximately hysteretic, that is, the damping loss factor η_E is approximately constant. Values ranging from 0.01 to 0.03 are representative of a wide range of construction materials.¹⁹ However, these figures are inappropriate for an entire building where damping may be an order of magnitude greater than the inherent material damping due to energy dissipation at structural joints. An overall loss factor of 0.1 may be used for typical building structures.

The inherent damping of isolation bearings varies according to their design. Typical loss factors range from 0.01, corresponding to undamped steel springs, to 0.1 for high-hysteresis rubber bearings.

The hysteretic damping model is also suitable for many soils over the frequency range and amplitudes typical of ground-borne vibration.²⁰ However, in practice, the behavior of building foundations is generally dominated by radiation damping due to the geometric spreading of vibration wavefronts. It is therefore more important that models represent the unbounded nature of the soil, such that radiation damping is correctly accounted for, than the precise nature of the material damping.

6.6 Representing the Vibration Source

Following the modeling process outlined earlier, the vibration source is represented by the vector \mathbf{u}_{bf0} . This contains the displacement amplitudes at nodes on the building–foundation interface in the absence of the building. The advantage of expressing the input in this way is that it need only be defined once, even if several different building designs are subsequently modeled. Vector \mathbf{u}_{bf0} may be calculated using the foundation model, excited by either an incoming vibration field or an explicitly modeled source such as an underground railway tunnel. Alternatively, the displacements may be specified to represent a known distribution in vibration amplitudes across a particular site.

6.7 Two or Three Dimensions

It may be necessary to limit the size of a numerical model and a decision is often required on whether two or three dimensions should be considered. Two-dimensional models are simpler and less demanding on computational resources. The disadvantage is that they assume the modeled system to be invariant in the antiplane direction and, particularly with foundation models, this limits the ability to correctly model wave propagation. For example, vibration that in practice may propagate on spherical wavefronts is constrained to cylindrical wavefronts and, therefore, attenuates less rapidly with distance, and foundations such as piles are represented as infinitely long barriers around which waves can no longer diffract.

The decision between two and three dimensions must be made on a case-by-case basis. In the case of a building with a repeating structure and a slab foundation, it should be possible to identify a representative section. A two-dimensional model may then be acceptable for predicting insertion performance. In general, three-dimensional models are required if predictions of absolute performance are to be made.

7 EXAMPLE CASE STUDY

This chapter concludes with an example case study concerning a new building that is to be constructed above an underground railway. Experience with an existing building on the neighboring site indicates that base isolation is necessary if the new building is to fulfill its intended function.

Here, attention is focused on the use of *side-restraint* bearings. The intention is to support the retaining walls of the basement cavity off the primary building structure, the aim of the side-restraint bearings being to minimize any “short-circuiting” of the base bearings. The objective of the modeling presented here is to predict the effect of the side-restraint bearings on the overall isolation performance.

7.1 Overview of Model

The building has a uniform repeating structure and a slab foundation in a substantially uniform soil. For this comparative study, a two-dimensional model is therefore deemed adequate, as illustrated in Fig. 5.

Figure 5 Two-dimensional model for investigating the effect of side-restraint bearings: (a) the building is represented by a portal frame, isolated from a boundary element representation of the ground by six base bearings (*) and two side-restraint bearings (>); and (b) the response of the building at 50 Hz to a buried harmonic force applied below the foundation slab.

The building is modeled using the dynamic stiffness method, which represents the primary structure as a series of coupled Euler beams and elastic columns. A finite element model would fulfill the same function provided care is taken to ensure an adequate number of elements are used. The isolation, which is designed to give an isolation frequency of 3.5 Hz, consists of six base bearings and two side-restraint bearings. Each one is modeled by three linear springs to account for its vertical, horizontal, and rotational stiffness.

The slab foundation is coupled to a boundary element representation of the ground, and the excitation from the underground railway is represented by a buried harmonic force. This is the simplest means of generating an incident vibration field that has the essential characteristics of the pressure and shear waves generated in practice.

7.2 Results

Following the process outlined earlier, the response of the building model may be calculated with and without isolation in place. The insertion performance may therefore be calculated for a system employing

Figure 6 Effect of side-restraint bearings on the power flow insertion gain of a base-isolated building. The results correspond to side-bearing stiffnesses of 1.00 (chained), 0.30 (solid), and 0.10 (dashed) times the stiffness of the base bearings. The case corresponding to no side-restraint bearings is shown in bold.

only base bearings and one with the addition of side-restraint bearings. Here, PFIG is used to provide a single measure of the average isolation performance throughout the building. This is achieved by using the predicted axial and bending stresses and strains at the bases of the building columns to calculate the total mean power flows entering the building.¹⁰

Figure 6 shows the variation with frequency in the PFIG when the dynamic stiffness of the side-restraint bearings is varied from 1.00 to 0.30 and 0.10 times the stiffness of the base bearings. In this example, as a spatial average, the isolation performance is limited below approximately 18 Hz due to local vibration modes of the building and foundation. Above 30 Hz, the effect of the side-restraint bearings is significant and minimizing the stiffness of these bearings maximizes the overall isolation performance. In this example, it appears that the side-restraint bearings are ideally located to deliver additional vibrational power to the building, and this outweighs any benefit from power leaving the building to be dissipated in the soil.

8 CONCLUSION

Base isolation of buildings is now well established as a means of minimizing the disturbance caused by urban ground-borne vibration. Residential buildings, office towers, cinemas, concert halls, and hospitals have all been constructed on sites otherwise deemed unacceptable due to their proximity to vibration sources such as busy roads and railways.

Isolation designs vary from building to building, and there is no single approach that is guaranteed to provide adequate performance for all structures. Performance is very much influenced by construction details and local site characteristics. Although a number of generic principles exist, engineers are therefore advised to evaluate designs using a suitable dynamic model. This should account for the mass, stiffness, and damping of the building's primary structure, along with the essential behavior of the foundation and the vibration source. Such models

enable designs to be optimized by predicting measures of insertion performance, particularly those based on vibrational power flow.

1 INTRODUCTION

Demand for air travel is projected to increase in coming years. However, virtually all major proposed changes in airports or airspace can elicit significant public comment, scrutiny, and often political, if not litigation-based, resistance. Usually, concerns about the noise produced by aircraft are cited as the basis for this resistance. As a result, to develop a uniform and defensible approach to airport design and to smooth the process of developing increased capacity at their airports, more and more nations have established a variety of specific noise prediction, assessment, and mitigation procedures.

These procedures are designed to address the primary noise sources and the situations in which they may become issues. These sources and situations become issues for reasons of public health and welfare or because they provoke public resistance to changes or insistence on improvements. Consequently, all noise analysis requires not only metrics to quantify aircraft noise but also associated criteria or guidelines to assess the effects or impacts of this noise on people. The procedures that are in place include metrics and criteria, analysis methods, and approaches to mitigation or control of the specific types of aircraft noise. These procedures include specific noise control approaches to reduce noise at the source and to minimize noise and land-use incompatibilities in affected communities.

2 AIRCRAFT NOISE SOURCES

With the vast array of aircraft, and the ground-support equipment in use today, it is helpful to understand the acoustic noise-producing elements of each of these sources. Such understanding provides a basis for judging the effectiveness of aircraft noise control strategies, both now and in the future. The subsequent discussion is organized by type of aircraft: (1) jet turbine powered, (2) propeller with either turbine or reciprocating power plants, and (3) rotary wing helicopters. Noise-producing ground-support equipment for each aircraft type will be treated within the appropriate subsection.

2.1 Jet-Turbine-Powered Aircraft

At airports where they operate, jet-turbine-powered aircraft departures and arrivals are usually the primary contributors to the aircraft sound exposure produced in adjacent communities. Typical commercial jets in use today (2005) produce on departure maximum A-weighted sound pressure levels ranging from the mid-70 to mid-80 dB at about 3 miles from brake release to mid-60 to mid-70 at about 7 miles. At 3 miles, these levels produce speech interference outdoors (A-weighted levels exceed 60 dB) for about 20 to 30 s for each departure.

The primary noise-generating mechanisms are the high-velocity jet exhaust gases mixing with the still air surrounding the jet flow, and blade passage tones from the compressor stages of the engine inlet. The jet noise-generating mechanism is the formation of turbulent eddies at the boundary between the high-speed jet gasses and the surrounding still air. Sound levels produced by these eddies have been shown to be proportional to roughly the seventh power of the jet velocity. Hence, even moderate reductions in the exhaust velocity where it meets the still air can reduce the generated sound power. The rotating vanes of the compressor fan produce tones. These tones can emanate from both the front and rear of the engine: either out the inlet nacelle or out the compressor bypass airflow at the rear of the engine. Noise control at the source for jet engines has concentrated on reducing the velocity of the jet flow that mixes with the ambient air and adding absorption treatment for tones in the inlet nacelle and in the bypass air ducts leading to the rear of the engine.

For example, engine manufacturers have come to rely less and less on the combustion gasses for thrust and more on *bypass airflow*. Inlet turbine compressors are now designed to provide the air needed by the combustor as well as additional compressed air for thrust. The additional thrust is achieved by routing a portion of the compressed air around the engine core (i.e., bypassing the combustor) and exhausting this air in a ring around the outside of the higher velocity jet gasses. The bypass air is of lower velocity than the engine exhaust, thereby lowering the strength of

the turbulent eddies and associated noise levels. This increase in *bypass ratio* has been responsible for a 10-dB or more reduction of takeoff sound levels.

Turbulence produced by the airframe itself as it moves through the air is also another source of noise. This noise is produced by turbulent eddies created by the interaction of various parts of the airframe (fuselage, wings, engines, etc.) with the still air they encounter in flight. Presently, the only flight regime where this source is not completely dominated by other sources is during landing, where engine thrust is small compared with other flight regimes. In the future, as jet engines become yet quieter, this airframe noise may be the factor that limits how quiet jet aircraft can be.

Despite the usual dominance of departures and arrivals in producing noise in surrounding communities, ground operations can be of concern as well. Start of takeoff roll, while the aircraft is on the ground, reverse thrust after landing, taxi operations, and use of auxiliary power units (APU) can affect communities located close to the runways, taxiways, or gates. Start of takeoff noise is cited as producing "rumble," causing houses to vibrate and produce rattle of windows or objects inside. Though A-weighted sound levels are used almost universally to quantify aircraft noise (see Section 3.1), A-weighting is likely to be inadequate for describing start of takeoff noise because of the significant presence of low-frequency energy.¹ The A-weighting network's attenuation of 30 dB or more below 50 Hz significantly deemphasizes the region where most residential structural resonances occur.

Taxi noise can be dominated by tones from the engine compressor. During taxi, jet engines are usually operated at flight idle power except during startup from a standing stop. Although taxi sound levels are low compared with in-flight noise, several aircraft waiting their turn for departure clearance can produce a continuous din easily heard at close-by residences.

On the ground, while parked at the gate, yet another source of noise is often present: the APU. When the engines are shut down, an alternative source of power must be available to power on-board electrical equipment. In the early days APUs were cart-mounted generators powered by reciprocating engines. Engine noise associated with these units was low to the ground, and the sound of these units often attenuated by low buildings before reaching neighboring airport communities. Currently, APUs are installed in the aircraft themselves to eliminate dependence on the availability of ground-based carts, especially at smaller airports. These APUs are turbine powered, installed in the rear of the fuselage, and generally exhaust from the tail cone of the aircraft. For today's transport aircraft, the ramifications are (1) this sound source has been elevated to 20 to 30 ft above ground level, well above many naturally occurring sound barriers such as one- and two-story buildings, and (2) they operate almost continuously during the turnaround time between flights. This source of noise can be a particular issue at hub airports where large numbers of aircraft are on the ground for periods of 1 to 2 h, several times a day.

2.2 Propeller Aircraft

Propeller aircraft noise is generally of concern only when there are no or only occasional jet operations over the same areas, when there is a runway used exclusively by propeller aircraft, or when they fly at low altitudes (about 500 to 1500 ft above ground) over quiet residential areas, as during touch-and-go practice patterns or as air tours over park or wilderness areas. These aircraft fall into two categories, piston and turbine powered. The larger transport category aircraft are all turbine powered. The two primary noise-generating sources are the propeller and the turbine itself. For all practical purposes the propeller dominates the noise levels in all flight regimes (takeoff, cruise, and landing), as well as during taxi on the ground. The propeller is a highly directional source, with a phenomenon called *thickness noise* being quite prominent within $\pm 10^\circ$ to 15° of the rotating plane of the propeller. Piston engine power plants are almost the exclusive province of private ownership, as well as some tour and transport operations serving very low demand markets. For piston-powered aircraft exhaust, tones can be a significant noise contributor in addition to the propeller.

2.3 Helicopters

Helicopters, also known as rotary wing aircraft, do not usually raise concerns when they operate from an airport with a mix of jet and propeller aircraft operations. Usually their operations are fewer and infrequent in comparison with the other aircraft operations at the airport. However, the obvious value of helicopters—their ability to fly into and out of constrained locations via arbitrary routes—can also be the source of public concern. At 1000 ft distance, they are about as loud as a large truck/lorry at 50 ft—A-weighted levels of 70 to 80 dB—so at lower altitudes, they can be easily heard in quiet residential areas, parks, and wildernesses and in the quieter areas of cities.

Helicopters fall into the same two categories as propeller aircraft, piston and turbine powered. In the case of helicopters, the main rotor supplies both the lift and forward thrust. The tail rotor provides directional stability and control. Both rotors are important noise contributors. As mentioned in the propeller aircraft discussion, rotating blades are highly directional sound sources. With the main rotor operating in the horizontal plane and the tail rotor in the vertical, helicopters can have highly complex, directional noise characteristics, in both the horizontal and vertical planes.

Although the main rotor produces a fundamental blade-vortex interaction tone of only 10 to 15 Hz, it is the higher harmonics of this tone that are audible to human observers. The sound is most pronounced within $\pm 10^\circ$ to 15° of the plane of the rotor. As the aircraft approaches the observer, the main rotor can also produce a separate phenomenon called *blade slap* (the familiar whop-whop-whop sound). In general, the heavier the aircraft the more prominent this sound becomes. The blade slap sound, another blade-vortex

interaction phenomenon, is highly directional in the vertical plane and is only forward propagating. Once the aircraft passes overhead, the observer blade slap is generally no longer audible.

The tail rotor, which operates at higher speeds than the main rotor and has been often referred to as the “necessary evil of helicopter design,” is often the dominant noise source, especially when the aircraft is approaching the observer. In an effort to improve reliability and reduce noise, some newer helicopters have been designed with no tail rotors (NOTARs). For these aircraft the directional thrust of the tail rotor is replaced by compressed airflow. An air intake forward of the tail boom provides the air source; the main engine operates a fan that compresses this air down a long tube the length of the tail boom; and at the end of the boom the tube makes a right turn providing the required lateral thrust. NOTAR aircraft can be significantly quieter than the tail rotor design but can be more expensive to produce.

3 AIRCRAFT NOISE METRICS AND CRITERIA

All aircraft noise analysis procedures are based on metrics that quantify the aircraft-produced sound levels or sound exposure levels as experienced on the ground. A threshold value is derived above which adverse noise effects may be expected or below which no adverse effects should occur.

3.1 Metrics or Indicators

There are two types of noise metrics used widely: one for the design and “certification” of specific aircraft types* and one for analysis of aircraft operations noise and its effects on noise-sensitive land use. The former is a measure of a single aircraft operation, used to specify required noise emission design requirements for a new or derivative aircraft type, while the latter, sometimes referred to as an indicator, is generally an integrated measure that accumulates the sound energy of all aircraft operations and is generally accepted to correlate with the effects aircraft noise may have on people.

The metric used universally for aircraft certification is the effective perceived noise level, abbreviated EPNL, with units of effective perceived noise decibels, or EPNdB (as opposed to decibels, or dB, used for all other metrics). It is a tone- and duration-corrected measurement of a single aircraft flyover, computed from measured one-third octave band sound levels.²

The most common metric for effects on humans is a measure of energy-averaged sound exposure, generally with weightings for different periods of the day. Use of A-weighting is either explicitly stated or understood. Different metrics may be used to

define levels that protect hearing, classroom learning, minimize annoyance, sleep disturbance, or speech interference. The discussion of effects presented here is restricted to the metrics and criteria that address annoyance and sleep disturbance.

3.1.1 European Union (EU) The EU uses the day–evening–night level, L_{den} , in decibels (dB), which is defined by the following formula in the European Noise Directive (END)³:

$$L_{den} = 10 \log \frac{1}{24} (12 \times 10^{L_{day}/10} + 4 \times 10^{(L_{evening}+5)/10} + 8 \times 10^{(L_{night}+10)/10}) \quad (1)$$

where L_{day} = A-weighted long-term average sound level as defined in International Organization for Standardization (ISO) 1996–2: 1987, determined over all the day periods of a year
 $L_{evening}$ = A-weighted long-term average sound level as defined in ISO 1996–2: 1987, determined over all the evening periods of a year
 L_{night} = A-weighted long-term average sound level as defined in ISO 1996–2: 1987, determined over all the night periods of a year

in which (a) the day is 12 h, the evening 4 h, and the night 8 h. Member states may shorten the evening period by 1 or 2 h and lengthen the day and/or the night period accordingly, provided that this choice is the same for all the sources and that they provide the commission with information on any systematic difference from the default option and (b) the start of the day (and consequently the start of the evening and the start of the night) shall be chosen by each member state (that choice shall be the same for noise from all sources); the default values are 07:00 to 19:00, 19:00 to 23:00, and 23:00 to 07:00 local time.

The EU also recognizes that some cases may benefit from the use of *supplementary noise indicators* and related limit values. Some examples for such use could be sources that operate for a small proportion of the time or that have unusual frequency characteristics, including tones, or that are impulsive in character.

3.1.2 United States In the United States, the primary metric for airport noise assessment is the day–night average sound level (or DNL, equation symbol L_{dn}) as established by the Environmental Protection Agency (EPA) in 1974⁴ and adopted by the Federal Aviation Administration (FAA) as interim in 1981 and finalized in December 1984.⁵ The definition of the day–night average sound level is similar to the EU’s L_{den} except it has two periods: Day is 07:00 to 22:00 and night is 22:00 to 07:00. The DNL metric adds a 10-dB penalty to the noise that occurs during the night hours. By definition, DNL is a 24-h metric.

Though not used directly by FAA procedures to assess aircraft noise effects, the FAA endorses

*All aircraft that are permitted to fly must pass specific certification requirements. In terms of noise, these requirements are based on detailed sound level measurements made during specific departure and approach procedures. Section 5 discusses these requirements in more detail.

use of “supplemental metrics” other than DNL to “describe aircraft noise impacts for specific noise-sensitive locations or situations and to assist in the public’s understanding of the noise impact.”⁶ These supplemental metrics may be measures of single-event levels or durations or integrated levels for periods shorter than 24 h. Their use may be for addressing effects such as sleep disturbance, speech interference, or audibility (e.g., for substantial restoration of natural quiet in Grand Canyon National Park).

3.1.3 World Health Organization For addressing annoyance and sleep disturbance, the World Health Organization (WHO) uses the “equivalent continuous sound pressure level,” which sums the “total energy over a selected time period (T)”⁷ (equation symbol $L_{Aeq,T}$). For daytime and evening annoyance assessment, T equals 16 h, while for sleep disturbance assessment, T equals 8 h. The WHO definition of $L_{Aeq,T}$ is consistent with definitions of that quantity found in ISO 1996/1-1982(E) and the American National Standards Institute (ANSI) S1.1-1994. The guidelines also include use of A-weighted maximum (fast meter response⁸) for assessment of sleep.

3.1.4 International Civil Aviation Organization The International Civil Aviation Organization (ICAO) does not specify metrics but provides a method for computation of various metrics for use by the *contracting states*—the 188 states that have agreed to the ICAO constitution, drawn up in 1944.⁹ See Section 5.

3.2 Effects or Impacts

Different countries/organizations have different approaches to determining the effects of aircraft noise on people. The term *impact* may have different meanings. In some cases, it identifies a threshold of unacceptable or undesirable effects, or it can mean that a threshold has been exceeded and specific actions to mitigate or alter the noise are required.

3.2.1 European Union The European Noise Directive provides for assessment of the harmful effects of noise as manifested by annoyance and sleep disturbance and offers dose–effect relations for this purpose.¹⁰

Annoyance Annoyance dose–effect relations have been developed for aircraft, road traffic, and railways and the results for aircraft are given in Table 1.¹¹ Member states may use the information as appropriate to their needs and some suggestions for use are provided. For example, three degrees of impact or acceptability might be developed. A highest level, which should not be exceeded or above which there should be no residential use, a middle range of conditional use suitable for goals of improvement, and a lowest level, which might serve as a target, or below which levels are completely acceptable and should be preserved. Values of Table 1 can be used to determine numbers of persons highly annoyed or

numbers annoyed when L_{den} is provided on maps of population distributions. Special sound insulation, shielding by buildings, differences in construction should be considered. Table 1 data are based on the responses of adult populations and are intended primarily for application to long-term stable situations. The relations are not recommended for use with taxiing noise.

Sleep The EU has also provided dose–effect relationships for assessing sleep disturbance.¹² The relationships are derived from surveys conducted in the Netherlands in which movement during sleep (motility), as determined by an actimeter worn on the wrist, is correlated with aircraft-produced noise events. This measured movement is found to correlate with change of sleep state, behavioral awakenings, and other measures of sleep disturbance, including responses to questions about sleep. Motility data were correlated with L_{night} yielding the relationship between maximum yearly noise-induced motilities, n_{max} and L_{night} :

$$n_{max} = N \times \left[\begin{array}{l} 0.0001233(L_{night} + 70.2 - 10 \log N) \\ - L_{Diff1} - L_{Diff2} \\ -0.007415(L_{night} + 70.2 - 10 \log N) \\ - L_{Diff1} - L_{Diff2} + 0.0994 \end{array} \right] \quad (2)$$

In Eq. (2), N is the annual number of nighttime aircraft noise events above the effect threshold of an outdoor A-weighted level of 53 dB, L_{Diff1} is the difference between L_{night} (measured away from reflecting surfaces) and the L_{Aeq} measured at the exterior facade of the bedroom, and L_{Diff2} is the difference between the outdoor L_{Aeq} at the exterior facade of the bedroom and the interior L_{Aeq} in the bedroom during sleep. Figure 1 shows the relationships between n_{max} and L_{night} for different numbers of nighttime events. This figure is derived by assuming an energy average sound exposure level (SEL) for all events. It also assumes that L_{Diff1} is 0 dB, and L_{Diff2} is 21 dB, as recommended by the EU document.

3.2.2 United States In the United States, early studies conducted for the U.S. EPA recommended that to minimize annoyance and sleep disturbance, the outdoor day–night sound level should be less than

Table 1 EU Recommended Relationships between Annoyance and Aircraft Noise

Aircraft Produced L_{den}	Percent of Exposed Population	
	Annoyed at All	Highly Annoyed

70	60	37
75	73	49

Figure 1 Average nightly noise-induced nighttime motilities.

60 dB.¹³ The U.S. EPA used this information and added an “adequate margin of safety” and identified a day–night average sound level of 55 dB as protective of public health and welfare.¹⁴

Annoyance More recently the Federal Interagency Committee on Noise (FICON) provided additional guidance on determining aircraft noise effects in terms of annoyance. FICON researched recent work and provided an updated dose–response curve for annoyance as a function of DNL from any transportation noise source. Table 2 summarizes this updated information.¹⁴

Sleep The successor to FICON, the Federal Interagency Committee on Aviation Noise (FICAN) published a synthesis of the then available sleep disturbance data and recommended the relationship given by Fig. 2.¹⁵ The FICAN 1992 curve of Fig. 2 represents the most conservative relationship for all the accumulated data—it is at or above the maximum percent awakening data at all points. Note that the sound levels on the horizontal axis are indoor levels. The awakening data are from on-site (as opposed to laboratory) studies that used either behaviorally confirmed awakening (the subject pressed a button when awakened) or

Figure 2 FICAN-recommended sleep disturbance dose–response curve.

motility within some specified latency from the noise event onset.

Land-Use Compatibility The FAA established guidelines for aircraft noise and land-use compatibility in 1981 for many land-use categories.¹⁶ These guidelines show residential land use, other than mobile homes and transient lodgings as compatible with yearly day–night average sound level (DNL) below 65 dB. Residential land use at levels between DNL 65 and 75 dB may be determined by a community to be allowed if the outdoor-to-indoor *noise level reduction* is at least between 25 and 30 dB to achieve an interior level of DNL 45 dB. Note that these are identified as guidelines because FAR Part 150 clearly defines land-use compatibility as a state and local government responsibility.

In examining new actions, *significant noise impact* occurs if a noise-sensitive area is projected to experience an increase in noise of DNL 1.5 dB or more at or above DNL 65 dB.¹⁷ Further, if such an increase occurs, noise-sensitive areas between DNL 60 and 65 dB should be examined for increases of 3 dB or more. If such increases occur, either above DNL 65 dB or between DNL 60 and 65 dB, additional analysis is

Table 2 FICON Recommended Relationship between Annoyance and Aircraft Noise

50	NA	2
55	NA	3
60	NA	7
65	NA	12
70	NA	22
75	NA	37

^a NA = not applicable.

required and mitigation measures should be considered for all areas of increase.

3.2.3 World Health Organization The WHO provides guidance for preventing critical health effects that can result from noise. Table 3 presents the guidance for dwellings. The levels shown, if not exceeded, are intended to prevent occurrence of the *critical health effect* for the most exposed receiver. The general WHO guidelines also note that, as suggested by the table, indicators based only on energy-type metrics (e.g., L_{Aeq}) are not sufficient to describe the protective noise environment. Such things as indoor reverberation time (for determining speech intelligibility), number and level of events, and low-frequency content should also be considered to fully describe the noise environment and to protect the critical health effect.

4 NOISE ANALYSIS PROCEDURES

4.1 Methods

Across the various organizations—the EU, the United States, and ICAO (the WHO does not examine the specifics of noise control)—the fundamental approach to analysis and management or control of aircraft noise is similar. All recommend a “balanced” approach that includes at least four ingredients: (1) noise control at the source (the aircraft), (2) land-use planning around airports, (3) noise abatement operating procedures for aircraft, (4) restrictions on operations.^{19–21} In addition to these four categories, in the United States, the FAA includes (5) airport layout²² and ICAO recognizes (6) noise charges.²³

To pursue this balanced approach, specific tools are required. First, metrics or indicators of noise must be identified (Section 3.1), noise effects or impacts in relation to the indicators need to be defined (Section 3.2), and a method for computing the values of the metrics in communities around airports is required. The following subsection elaborates on the “balanced” approach, and the last subsection discusses the various computational methods.

4.2 Balanced Approach

4.2.1 European Union The EU recognizes the balanced approach as defined by ICAO²¹ but links it with a recognition that to be effective in achieving sustainable noise reduction, more stringent noise

standards for manufacture of aircraft, combined with action to take noisy aircraft out of service, will also be necessary. Specifically, Directive 2002/30/EC²¹ provides guidance on “the establishment of rules and procedures with regard to the introduction of noise-related operating restrictions at Community airports.”

4.2.2 United States The Aviation Safety and Noise Abatement Act of 1979 (Public Law 96–193) authorized the FAA to award grants under the Airport Improvement Program (AIP) for noise mitigation projects. The FAA responded by promulgating 14 CFR Part 150, see discussion on FAR Part 150 below. As of the end of 2003, more than \$3.6 billion of AIP funding has been spent on developing and implementing Part 150 studies by more than 250 airports in the United States.

Source Noise Control—Aircraft Certification and Phase Out

The FAA’s method for determining aircraft source levels and the phase out of the louder aircraft have been specified in federal regulations, 14 CFR Part 36 and Part 91. In 1990, the U.S. Congress passed the Airport Noise and Capacity Act (ANCA),²⁴ which set a schedule for phase out of all stage 2 aircraft weighing more than 75,000 lb by December 31, 1999 (all stage 1 aircraft having been previously prohibited from operation in the United States.). The phase-out schedule is codified in 14 CFR Part 91. Currently, there is no proposal to phase out stage 3 aircraft, although new stage 4 noise limits have already been established.

FAR Part 150: Airport Noise Compatibility Planning

As part of the effort to encourage airport and land-use noise compatibility, the FAA makes funding available to airports for noise mitigation through its Part 150 Study program. In order to obtain federal monies for noise assessment, impact mitigation, and land-use compatibility, an airport is required to assess the existing and future noise environment through a Federal Aviation Regulation (FAR) Part 150 Study. Although airports are not required to conduct FAR Part 150 studies, many do in order to obtain this federal assistance. FAR Part 150 studies result in: (1) a noise exposure map (NEM), which documents the existing and future (minimum 5-year) noise exposure with no mitigation; (2) a noise compatibility program

Table 3 WHO Guideline Values for Community Noise in Specific Environments¹⁸

Specific Environment	Critical Health Effect	L_{Aeq} [dB(A)]	Time Base (h)	L_{Amax} Fast (dB)
Outdoor living area	Serious annoyance, day and evening	55	16	—
	Moderate annoyance, day and evening	50	16	—
Dwelling, indoors	Speech intelligibility & moderate annoyance, day and evening	35	16	
Inside bedrooms	Sleep disturbance, nighttime	30	8	45
Outside bedrooms	Sleep disturbance, window open (outdoor values)	45	8	60

Source: From Ref. 18.

(NCP), which identifies specific actions to minimize or eliminate the existing noise impacts in surrounding communities. In developing the NCP, the airport is to examine components that constitute the balanced approach and include land acquisition, construction of barriers, soundproofing, preferential runway use, flight procedures, and restrictions on the use of the airport. The NCP also includes the results of the program by providing an NEM with the recommended NCP measures in place.

4.2.3 International Civil Aviation Organization

In 2001, the ICAO Assembly endorsed the concept of a balanced approach to aircraft noise management (see references in Ref. 20). Within ICAO, the Committee on Aviation Environmental Protection (CAEP) developed the requisite guidance material.²⁵ CAEP meets annually, and from each meeting, publications providing guidance are produced. (In terms of nomenclature, e.g., CAEP/5 indicates the fifth meeting of CAEP.) Some of this guidance and associated publications are summarized in the following paragraphs.

Source Noise Control—Certification Certification procedures and requirements are contained in Annex 16, Environmental Protection, Volume I, Aircraft Noise to the Convention on International Civil Aviation, while practical guidance to certifying authorities on implementation of the technical procedures of Annex 16 is contained in the Environmental Technical Manual on the Use of Procedures in the Noise Certification of Aircraft (Doc 9501). For ICAO, aircraft are designated as Chapter 1, not noise certified, Chapter 2, certified in accordance with the requirements of Annex 16, Volume 1, Chapter 2, and so forth for Chapter 3 and Chapter 4 aircraft. (These designations correspond with the U.S. FAA designations of stage 1, stage 2, stage 3, and stage 4.)

Land-Use Planning Land-use planning guidance can be found in Annex 16, Volume I, Part IV, and Airport Planning Manual, Part 2, Land Use and Environmental Control (Doc 9184). It is important that member states ensure that the potential reductions in noise levels to be gained from the introduction of quieter aircraft, particularly those complying with the new Chapter 4 standard, are not avoidably compromised by inappropriate land use or encroachment.

Operational Procedures Description of preferential runways and routes, as well as noise abatement procedures for takeoff, approach, and landing are contained in Annex 16, Volume I, Part V, and in Procedures for Air Navigation Services, Aircraft Operations (PANS-OPS, Doc 8168), Volume I, Flight Procedures, Part V. On the basis of recommendations made by CAEP/5, new noise abatement takeoff procedures became applicable in November 2001.

Operating Restrictions In the case of Chapter 2 aircraft, the ICAO Assembly in 1990 urged member states not to restrict aircraft operations without considering other possibilities first. It then provided a basis on which states wishing to restrict operations of

Chapter 2 aircraft may do so. States could start phasing out operations of Chapter 2 aircraft from April 1, 1995, and have all of them withdrawn from service by March 31, 2002. However, prior to the latter date, Chapter 2 aircraft were guaranteed 25 years of service after the issue of their first certificate of airworthiness. Thus, Chapter 2 aircraft that had completed less than 25 years of service on April 1, 1995, were not immediately affected by this requirement. Similarly, wide-body Chapter 2 aircraft and those fitted with quieter (high bypass ratio) engines were not immediately affected after April 1, 1995. Many countries including Australia, Canada, the United States, and many in Europe have nevertheless taken action on the withdrawal of operations of Chapter 2 aircraft at their airports, taking due account of the Assembly's resolution. This withdrawal has had a substantial effect in reducing noise levels at many airports. The benefits of removing Chapter 2 aircraft have now been largely achieved.

In the case of Chapter 3 aircraft, the ICAO Assembly in 2001 urged member states not to introduce any operating restrictions at any airport on Chapter 3 aircraft before fully assessing available measures to address the noise problem at the airport concerned in accordance with the balanced approach. The Assembly also listed a number of safeguards that would need to be met if restrictions are imposed on Chapter 3 aircraft. For example, restrictions should be based on the noise performance of the aircraft and should be tailored to the noise problem of the airport concerned, and the special circumstances of operators from developing countries should be taken into account (Appendix E of Assembly Resolution A33-7).

Noise Charges The ICAO's policy with regard to monetary noise charges was first developed in 1981 and is contained in ICAO's Policies on Charges for Airports and Air Navigation Services (Doc 9082/6). The ICAO recognizes that, although reductions are being achieved in aircraft noise at the source, many airports need to apply noise alleviation or prevention measures. The ICAO considers that the costs incurred may, at the discretion of states, be attributed to airports and recovered from the users. In the event that noise-related charges are levied, the ICAO recommends that they should be levied only at airports experiencing noise problems and should be designed to recover no more than the costs applied to their alleviation or prevention; and that they should be nondiscriminatory between users and not be established at such levels as to be prohibitively high for the operation of certain aircraft.

Practical advice on determining the cost basis for noise-related charges and their collection is provided in the ICAO Airport Economics Manual (Doc 9562), and information on noise-related charges actually levied is provided in the ICAO Manual of Airport and Air Navigation Facility Tariffs (Doc 7100).

4.3 Airport Noise Modeling

Countries involved in aircraft noise analysis use or have developed and use computer programs that

combine the noise produced by all aircraft operations at an airport, generally to produce contours of equal noise exposure or level using the metric or indicator that is to be used for assessment, see Section 3. Figure 3 presents a typical contour set.

Typically, national or international organizations have developed the general guidelines and algorithms for aircraft noise computation. Then individual nations turn these guidelines into specific computer programs. ICAO provides guidance in its Circular 205,²⁶ the Society of Automotive Engineers (SAE) Committee A-21, Aircraft Noise Measurement, developed Aerospace Information Report 1845²⁷ and the EU recommends use of ECAC/CEAC Doc 29, Report on Standard Method of Computing Noise Contours around Civil Airports.²⁸ (Currently, all documents are undergoing review and updates.) The variables that must be included or input into one of the programs are considerable in number and can be found in one of the user manuals. The model output typically includes, at a minimum, contours of equal noise exposure, as mentioned. The models can also produce single-event noise metrics, and these are often computed to help the public understand the noise effects of the modeled operations or to compare with impact or health effect guidelines.

Each of these models requires an accurate account of the aircraft activity at the facility for which the model is to determine the noise exposure. It is critical that the modeler know the exact number of operations for every aircraft type operating at the facility and for each type of operation conducted, that is, arrival, departure, touch-and-go, runup, and so forth. Some states require this analysis be conducted for an annual average day. Therefore, it is imperative that data are collected for operations over a period of 1 year and

then the number of operations is divided by 365 days before inputting into the model.

5 NOISE CONTROL AT THE SOURCE

Aircraft noise control at the source has two components. First, for all manufacture of aircraft, specific noise testing or certification procedures and associated limits are defined. Second, the louder aircraft are phased out of operation over time.

5.1 Quieting of Aircraft

These procedures and limits apply at three specific measurement locations: one under a departure path, one laterally to the side of the departure path, and one under an arrival path. During measurements, weather and atmospheric conditions must fall within specific ranges, the aircraft must be operated in defined ways, and detailed methods are provided for computation of the required metric, EPNL (see references in Ref. 2).³² Limits are specified by maximum gross takeoff weight and number of engines. Figure 4 presents the limits that define FAA's stage 1, stage 2, and stage 3 (ICAO's Chapter 1, Chapter 2, and Chapter 3) aircraft. Any aircraft above the stage 2 limit is stage 1.

There is also a stage/Chapter 4 certification for aircraft. On June 27, 2001, at its 163rd session, the ICAO unanimously approved the adoption of the new Chapter 4 noise standard in Annex 16. In the United States, the FAA also has accepted this certification limit. The new noise standard will apply to any application for new type designs submitted on or after January 1, 2006, for countries that use Annex 16 as its noise certification basis. Briefly, conformance with Chapter 4 has two basic components: (1) None of an airplane's maximum noise levels [flyover, lateral (sideline), and approach] may be greater than the maximum permitted

Figure 3 Typical noise contours for an airport.

Figure 4 Certification limits for aircraft.

noise levels for Chapter 3 airplanes, as defined in Annex 16. (2) To determine stage 4 compliance, an airplane's maximum flyover, lateral and approach noise levels are each subtracted from the stage 3 maximum permitted noise levels. The differences obtained are the noise limit margins, to be used as follows:

1. When the three margins are added together, the total must be 10 EPNdB or greater.
2. When any two of the margins are added together, the sum must be 2 EPNdB or greater.

5.2 Phase Out of Louder Aircraft

The second component of noise control at the source is the phase out of the louder aircraft. To date (2005) stages/Chapters 1 and 2 aircraft have been completely phased out of operation in many countries and are being phased out in others.

6 AIRPORT-SPECIFIC NOISE CONTROL MEASURES

The balanced approach also includes land-use planning around airports, noise abatement operating procedures, restrictions on operations, and the airport layout. Additionally, monitoring systems and community outreach can aid in the efforts to reduce the effects of airport noise on communities.

6.1 Land-Use Strategies

Land-use strategies are directed at ensuring noise-compatible land use surrounds the airport. The most effective land-use strategies must include working with

local jurisdictions to deter and/or prohibit the development of incompatible noise-sensitive land uses within the airport environs. This strategy can include zoning and building code changes that either prevent incompatible uses or require that sufficient sound insulation be part of building design. Another strategy often employed by airports to eliminate future incompatibilities is the acquisition of vacant land in potentially incompatible areas. The strategies used for addressing existing incompatibilities are typically: (1) relocation of residents, business, and schools resulting in airport land acquisition after the relocations and (2) requiring remaining property owners sign an aviation easement allowing for the use of the airspace above the property. The second is often implemented in conjunction with sound insulation programs.

6.1.1 Sound Insulation Programs Residential sound insulation programs and institutional sound insulation programs, predominantly for schools, are intended to reduce the interior noise levels of structures to minimize speech and/or sleep disruption. Design goals are required for sound insulation. Goals for residences may be determined by speech interference or sleep disturbance criteria, such as those of Section 3.2 or by the requirements for a satisfactory teaching environment when sound-insulating schools. House construction varies with climate and local traditions, and premodification measurements and analysis are advisable to determine design, and postmodification measurements help ensure success.

6.1.2 Noise Barriers Noise barriers can be used to shield noise-sensitive land uses from aircraft

operations noise. See Chapter 58. Noise barriers are rarely built at airports since most of the noise exposure occurs when aircraft are above the ground and above any reasonably sized barrier. However, some communities are exposed to noise produced by ground operations of aircraft, such as start-of-takeoff roll, thrust reverse, taxi or ramp activities, and ground engine runups. One of the most successful uses of barriers in airport settings has been the installation of ground engine runup enclosures (GREs), which are provided by some airports for performance of maintenance engine runups.

6.2 Operational Procedures

Operational procedures for noise abatement are essentially ways for aircraft to use an airport that reduce the noise exposure of noise-sensitive areas. These procedures can include use of runways, specific cockpit procedures for arrival and/or departure, and routes or flight tracks flown for arrival and departure. Design of feasible, effective procedures requires full involvement by air traffic control personnel, pilots, use of modeling procedures and analysis to estimate effectiveness, and often a test period to determine if they are, in fact, practical and safe. Citizen involvement may be beneficial as well.

6.2.1 Preferential Runway Use Preferential runway use is designed to put aircraft operations on particular runways to minimize aircraft operations over populated areas. Design will require analysis of average wind conditions to determine maximum possible use of the various runways. Air traffic procedures used to determine which should be the active runway(s) may need modification to ensure maximum use of the preferred runway(s). Procedures for monitoring the ongoing runway use may also be desirable to determine the success of a preferential runway use program.

6.2.2 Cockpit Procedures Cockpit procedures are specific flight procedures designed to reduce the noise levels experienced on the ground. Specific noise abatement departure procedures (NADPs) have been developed by many airlines to address two different types of situations: one where the noise-sensitive areas are “close” to the airport and one where the noise-sensitive areas are “distant” from the airport. Usually, detailed modeling, including working with pilots or airlines to develop modeled approximations of the procedures, is required to understand the location and amount of the benefits provided. Cockpit procedures can also be used during aircraft arrival. Investigations have found that a *continuous descent approach*, or CDA—descending the aircraft at a nearly constant angle from a fairly high altitude (about 6000 ft above ground)—can reduce noise heard on the ground by eliminating the thrust changes used in the more common “stepped” approach. CDA procedures are still under investigation at this writing with regards to air traffic control implications.

6.2.3 Flight Track Geometry and Flight Track Usage Changes to flight track geometries and/or flight

track usage can be designed to move aircraft over less populated areas. Changing flight track corridors or use, however, requires full involvement of the air traffic controllers responsible for managing the airspace. Especially in congested airspace, maintaining minimum separations between the traffic flows is paramount for safety. Moving flight tracks can have a domino effect requiring other changes to the airspace, which may or may not be feasible. Modeling will provide estimates of benefits, and test periods may be necessary.

6.3 Airport Layout Improvements

Planning for major changes at an airport can provide an opportunity to consider layout improvements that would result in the reduction of noise exposure of sensitive areas. Generally, airport layout changes may be used to move aircraft operations (whether taxi, ground, departure, or arrival operations) away from noise-sensitive areas. For example, an airport may decide to lengthen a runway and displace the arrival and departure threshold at the other end of the runway. Start of takeoff and use of thrust reversal could be moved further onto airport property and away from noise-sensitive receivers near the runway end. Another change could be alteration of taxiways to move these ground operations away from adjacent residents. Design and placement of on-airport buildings could shield near-by communities from some types of aircraft ground operations noise.

6.4 Airport Use Restrictions

The European Union, the U.S. FAA, and ICAO documents all recognize there may be situations when restricting use of an airport by all or some aircraft types can be an important means to reduce noise exposure. All organizations caution that the costs, both to the traveling public and to individual aircraft operators, should be closely considered when developing any such restrictions. A rigorous approach would include clear determination of criteria for effects, analysis, and rank ordering of alternative methods, including restrictions, to reduce the effects and costs of the alternatives.

6.5 Aircraft Noise and Operations Monitoring Systems

Aircraft noise and operations monitoring systems (NOMS) have become increasingly common in recent years as citizens ask to have measured information about aircraft operations and noise levels, and as some airports regularly update their noise contours. These systems permit airports to continuously assess aircraft noise and operations and respond to citizen complaints. NOMS are used not only to assess airport noise but also can be used to educate the community about aircraft noise, respond to noise complaints, and monitor the implementation of noise mitigation measures.

The NOMS were first designed as aircraft noise measurement systems consisting of portable and permanent noise monitors strategically located throughout the airport environs. Flight tracking capability has been added by acquiring aircraft position data, usually from the local air traffic radar system. Flight tracking data

helps ensure that the noise captured by the noise monitors and identified as aircraft-produced noise is actually generated by an aircraft operation and not some other community noise source. Additionally, this flight track and flight identification information can be used to efficiently provide input to the aircraft noise modeling process. Airports can obtain integrated noise model (INM) preprocessors that will take the flight information and generate INM input files to compute daily, weekly, monthly, quarterly, and annual noise exposure contours for a relatively quick and efficient means of assessing the historical noise at their facility.

6.6 Community Outreach

Many airports have found community outreach, involvement, and education can be as effective and sometimes more effective than the measures discussed above. Outreach may take many different forms, but the most common avenues for providing this community involvement are: setting up and supporting an airport noise office with adequate and capable staff, acquiring a NOMS, setting up and being a member of a standing airport community noise committee or roundtable, and regularly reporting to the community the progress of the noise mitigation measures and the noise compatibility program.

CHAPTER 126

OFF-ROAD VEHICLE AND CONSTRUCTION EQUIPMENT EXTERIOR NOISE PREDICTION AND CONTROL

Lyudmila Drozdova, Nickolay Ivanov, and Gennadiy H. Kurtsev
Department of Environmental Engineering
Baltic State Technical University
St. Petersburg, Russia

1 INTRODUCTION

Off-road vehicles and construction equipment are used for earthmoving, road works, building and road construction, excavation, and the laying of pipes and cables. Off-road vehicles and equipment are normally powered by diesel engines and, in some cases, electric motors. Compressors provide compressed air for use on construction sites and can be mobile or stationary.

Off-road vehicles and construction equipment are significant environmental noise sources that cause annoyance, risks of hearing damage, and sleep disturbance in nearby residential areas. A-weighted sound pressure levels measured at a 15-m distance from an off-road vehicle during its operational cycle can reach 70 dB to 85 dB. Even at a short distance, the A-weighted noise levels emitted by off-road vehicles and construction equipment can be as much as 15 dB to 30 dB higher than permissible levels. Excessive noise levels are also noted at distances up to several hundred metres from working construction machinery. Off-road vehicles and construction equipment cause disturbance to people similar to that caused by automobiles, railways, and aircraft.

2 DESIGN FEATURES AND MAIN NOISE SOURCES

The outlines of most widely used off-road vehicles and construction equipment and main noise sources are represented in Fig. 1. Main noise sources of the off-road vehicles are an engine, exhaust and intake systems, tracks, engine cooling fans, hydraulic system, compressors of movable compressors and other noise, and vibration generating machinery (e.g., mill cutter, vibrating roller, and others). Table 1 gives the average acoustical characteristics of the main noise sources of construction vehicles and movable compressors.¹

The contribution of a noise source into the noise generation process depends, first of all, on noise source acoustical characteristics but also on the distance from the noise source to the specific point (receiver), on the noise source size and its location at the machine, and on available noise reduction means and their effectiveness.

3 OFF-ROAD VEHICLES EXTERIOR NOISE EMISSIONS REQUIREMENTS

In most countries A-weighted sound power level emitted by a vehicle (in dB) is used as a standardized

Figure 1 Schemes of off-road vehicles and construction equipment: (a) excavator, (b) tractor with dozer equipment, (c) backhoe loader, and (d) movable compressor; (1) engine, (2) enclosure, (3) muffler, (4) engine intake, (5) cab, and (6) sound absorption coating.

parameter. At the same time sound pressure levels are also used for normalization in some countries. For example, exterior noise limitation accepted in Russia and in the Commonwealth of Independent States is A-weighted sound pressure level of 85 dB measured at the distance of 7.5 m from a machine. In United States specific exterior sound requirements on off-road machines are related to state laws or community noise ordinances. The specific levels vary and are often expressed in terms of day and night sound pressure level. The European Community (EC) actual and expected noise limitations are declared in Directive 2000/14/EC of the European Parliament.² These limitations are presented in the Table 2.

In Germany, in addition to the European norms, the Federal Environmental Agency introduces the Environmental Label (Blue Angel) for off-road vehicle manufacturing companies (Table 3). This label may be awarded to products whose noise emissions are 10 dB or lower, on average, than EC Directive noise limitations.³ Noise requirements of the Blue Angel label are the strongest among recently accepted limitations for off-road vehicles.⁴

Table 1 Acoustical Characteristics of Main Noise Sources of Off-Road Vehicles and Movable Compressors

Noise Source	A-Weighted Sound Power Level (dB)	Character of Noise Spectrum Emitted by the Noise Source
Engine body	100–110	High frequency ^a
Engine exhaust (with a muffler)	91–98	Low frequency ^b
Engine intake (with a muffler)	85–90	Low frequency
Engine cooling system fan	98–102	Medium frequency ^c
Tracks	89–92	Medium frequency
Vibrating roller	100–105	High frequency
Hydraulic motors and pumps	95–97	High frequency
Compressor	97–100	High frequency

^aHigh-frequency components are dominant in the sound pressure level spectrum.

^bLow-frequency components are dominant in the sound pressure level spectrum.

^cMedium-frequency components are dominant in the sound pressure level spectrum.

As follows from the analysis, there is no uniform approach to be used in the exterior noise limits formulation throughout the world. Consideration of community noise limits may be applied to compare noise emissions of different off-road vehicles. In many countries community noise limits are declared in terms of equivalent continuous A-weighted sound pressure levels and are equal to 55 dB for daytime and 45 dB for nighttime.⁵ Nowadays very few off-road vehicles meet these community noise limits, so machine manufactures in cooperation with acousticians have the challenge of finding innovative, state-of-the-art exterior noise reduction approaches.

4 MEASUREMENT OF EXTERIOR NOISE EMITTED BY OFF-ROAD VEHICLES AND CONSTRUCTION EQUIPMENT

4.1 Measurement of Exterior Noise Emitted by Off-Road Vehicles

Exterior noise measurement procedures are described in International Organization for Standardization (ISO) standards.^{6,7} Measurements may be carried out in dynamic and stationary test conditions. The exterior noise is characterized by A-weighted sound power level (L_{WA}) estimated based on measured equivalent continuous A-weighted sound levels averaged over the measurement surface over the whole measurement period.

Sound level measurements followed by determination of the emitted sound power level are carried out in six microphone positions at the hemispheric surface. The choice of the hemisphere radius depends on the basic machine length (L). The hemisphere radius is determined as follows:

$r = 4$ m when $L < 1.5$ m.

$r = 10$ m when $L \geq 1.5$ m but less than 4 m.

$r = 16$ m when $L > 4$ m.

The A-weighted sound power level, L_{WA} , emitted by a machine is determined as follows:

$$L_{WA} = \bar{L}_{pAeq,T} - K + 10 \log \frac{S}{S_0} \quad \text{dB} \quad (1)$$

$L_{pAeq,T}$ = equivalent A-weighted continuous sound pressure level averaged over the measurement surface, dB

K = environmental correction

S = area of the hemispherical measurement surface, in square metres, i.e., $S = 2\pi r^2$

$S_0 = 1 \text{ m}^2$

Table 2 European Union Requirements on the Noise Emissions of Off-Road Vehicles and Construction Equipment

Vehicle type	Net Installed Power P (kW)	Permissible A-Weighted Sound Power Level (dB)	
		Stage I From 03.01.2002	Stage II From 03.01.2006
Compacting machines (vibrating rollers, vibratory plates, etc.)	$P \leq 8$	108	105
	$8 < P \leq 70$	109	106
Tracked dozers, loaders, excavator-loaders	$P > 70$	$89 + 11 \log P$	$86 + 11 \log P$
	$P \leq 55$	106	103
	$P > 55$	$87 + 11 \log P$	$84 + 11 \log P$
Wheeled dozers, loaders, excavator-loaders, mobile cranes, graders	$P \leq 55$	104	101
	$P > 55$	$85 + 11 \log P$	$82 + 11 \log P$
Tower cranes	–	$98 + \log P$	$96 + \log P$
	$P \leq 15$	99	97
Compressors	$P > 15$	$97 + 2 \log P$	$95 + 2 \log P$
	$P \leq 15$	96	93
Excavators	$P > 15$	$83 + 11 \log P$	$80 + 11 \log P$
	$P \leq 15$	96	93

Table 3 Blue Angel Noise Criteria

Machine Type	Category, Standardized Nominal Airflow (Q), m ³ /min, Installed Power (P), kW	Noise Emission Limits (A-Weighted Sound Power Level), dB
Track Vehicles, Except Excavators	$P \leq 60$	99
	$P > 60$	$80 + 11 \log P$, but less than 101
Wheeled Dozers, Loaders	$P \leq 39$	97
	$P > 39$	$79 + 11 \log P$, but less than 101
Compressors	$Q \leq 5$	88
	$5 < Q \leq 10$	89
	$10 < Q \leq 30$	91
	$Q > 30$	93
Excavators	$P \leq 14$	91
	$P > 14$	$78 + 11 \log P$, but less than 101
Tower Cranes	$P < 15$	86
	$15 \leq P < 30$	88
	$P \geq 30$	90

Equivalent A-weighted continuous sound pressure level, $L_{pAeq,T}$, is estimated by the following equation:

$$\bar{L}_{pAeq,T} = 10 \log \left[\frac{1}{N} \sum_{i=1}^N 10^{0.1 L_{pAeqi}} \right], \text{ dB} \quad (2)$$

L_{pAeqi} = measured value of the equivalent A-weighted continuous sound level, dB, resulting from the i th point at the hemisphere (reference sound pressure is 2×10^{-5} Pa)

N = is the number of microphone positions ($N = 6$ for this test method)

The background noise level in each measurement position is supposed to be at least 10 dB lower than the noise level emitted by the machine under the test.

4.2 Measurement of Exterior Noise Emitted by Movable Compressors

Methods of movable compressors exterior noise measurements are presented in the ISO standard.⁸ Averaged octave sound pressure levels (dB) and A-weighted sound pressure levels (dB) measured at 7 m distance from a movable compressor are used as an acoustical characteristic of a compressor. Sound pressure levels are controlled in five microphone positions located in four main directions rectangular to the compressor side panels, and the fifth microphone location is chosen in the direction where controlled sound

pressure level is maximal. Measurement positions are located at 1.5 m distance from the underneath surface where the movable compressor is installed. Measurements are carried out in the free sound field. There shall not be any obstacle at 25 m distance from the compressor, whose size is comparable to the size of the movable compressor.

5 ACOUSTICAL CHARACTERISTICS OF OFF-ROAD VEHICLES AND MOVABLE COMPRESSORS

Exterior noise emitted by off-road vehicles depends on their acoustical characteristics, on the number of noise sources, and on the composition and effectiveness of noise reduction means. Table 4 presents noise characteristics of some vehicles and tractors.¹

All off-road vehicles considering their acoustical characteristics may be divided into three main groups. The first group consists of wheeled vehicles (excavators, loaders, graders) where the engine is the dominant noise source. These vehicles are characterized by the lowest sound power levels (among other off-road vehicles), and the difference between dynamic and stationary operating modes is not higher than 1 dB to 2 dB.

The second group consists of track vehicles in which the contributions of tracks and engine to exterior sound field are comparable. Noise level emitted by such machines in dynamic operating mode is 3 dB to 4 dB higher than in stationary mode because of increasing track contribution during dynamic cycles.

Table 4 Exterior Noise Levels of Construction and Transportation Vehicles and Tractors

Group Number	Vehicle Type	Operating Mode	A-Weighted Sound Power Level (dB)
1	Wheeled loaders, excavators, graders	Stationary	96–102
		Dynamic	97–105
2	Tracked tractors and dozers	Stationary	100–102
		Dynamic	103–106
3	Vibrating rollers	Stationary	97–99
		Dynamic	109–111

The third group consists of vehicles in which vibration or impact generation tools (e.g., vibrating rollers) or other noise-generating mechanical facilities are the dominant noise sources. Noise level emitted by such vehicles in stationary operating mode is 10 dB lower than noise emitted in dynamic mode. Spectrum of the first group is characterized by the dominance of the low- and medium-frequency components, the second group is characterized by dominant contributions in the high-frequency range, and the third group is characterized by the medium- and high-frequency spectrums.

Noise emitted by movable compressors depends on the type of a power plant—an engine (diesel or gas) or an electric motor—on the type of compressor (piston, membrane, rotation, blade, or screw type), and on the mode of operation since the power plant plays the main role in noise generation processes.

Movable compressors with volume flow rates varying from 2.5 m³/min up to 5 m³/min are the most widely applied (they are about 40% of the overall quantity of produced compressors). Movable compressors characterized by the volume flow rates varying in the range of 7.5 to 15 m³/min are only about 18% of the overall quantity of produced compressors.

Noise emitted by compressors with engine power plants is higher than noise emitted by compressors with electric motor power plants with the same volume flow rate. Thus A-weighted sound pressure level at 1 m distance is 101 dB for diesel-engine-driven compressors, and it is 96 dB for gas-engine-driven compressors, and it is 93 dB for electric-motor-driven compressors. Noise emitted by the diesel engine and electric-motor-driven compressors has high-frequency character and noise of gas compressors has low-frequency spectrum, mostly because of the contribution of the exhaust noise. Movable compressor noise also increases with an enhancement of the volume flow rate since the engine power consumed by the compressor is higher.

A-weighted sound pressure levels emitted by non-sound-proofed compressors with volume flow rates up to 10 m³/min are usually in the range of 80 dB to 90 dB. Most of modern leading compressor manufacturing companies produce movable compressors in sound-proofed varieties (Table 5).¹

Table 5 Acoustical Characteristics of Movable Compressors at 7-m Distance

Movable Compressor Type	Drive Type	Volume Flow Rate (m ³ /min)	Sound Pressure Level (dB)
Non-sound-proofed	Diesel	5.2	89
Non-sound-proofed	Diesel	10.5	92
Non-sound-proofed	Electric motor	5.2	80
Non-sound-proofed	Electric motor	10.0	84
Non-sound-proofed	Gas	5.2	86
Sound-proofed	Diesel	5.0	70
Sound-proofed	Diesel	10.6	75
Sound-proofed	Electric motor	5.0	58

6 NOISE GENERATION PROCESSES AND PREDICTION OF EXTERIOR NOISE

An example of the calculation scheme of the exterior noise emitted by a tracked dozer is presented in Fig. 2. Main noise sources and noise propagation paths are as follows: track noise (L_{tr}), engine body noise penetrating from the engine compartment through the enclosure walls (L_{eng_enc}), engine intake (L_{int}), and exhaust noise (L_{exh}).

The exterior noise field is formed by the total contributions of all above-mentioned noise sources and may be determined by the following equation¹:

$$L^{ext} = 10 \log \left(10^{0.1L_{eng_enc}} + 10^{0.1L_{exh}} + 10^{0.1L_{int}} + 10^{0.1L_w} \right) \text{ dB} \quad (3)$$

The first term of Eq. (3) is estimated as follows¹:

$$L_{eng_enc} = L_{W_{enc}}^{total} + 10 \log \left(\frac{\chi_{enc}}{S_{enc_total}} + \frac{4\psi_{enc}}{B_{enc}} \right) - 10 \log \frac{\sum_{i=1}^m S_{enc,i}}{\sum_{i=1}^m S_{enc,i} \times 10^{-0.1(SI_{enc,i} + t_{enc_i})}} + 10 \log \frac{\sum_{i=1}^m S_{enc,i}}{S_{enc}} - 15 \log R_{enc} - x \text{ dB} \quad (4)$$

where $L_{W_{enc}}^{total}$ = total acoustical power emitted within the enclosure, dB

χ_{enc} = coefficient of the effect of the near sound field of noise source (engine body)

ψ_{enc} = is the coefficient of the sound field diffusivity violation under the enclosure;

S_{enc_total} = is the total area of inner structural panels of the enclosure (inside the engine compartment), m²

Figure 2 Calculation scheme for tracked dozer exterior noise prediction: (1) engine body noise penetrating from the engine compartment through the enclosure walls, (2) internal combustion engine exhaust noise, (3) intake noise, (4) track noise.

B_{enc} = is the acoustical enclosure constant, m^2 , estimated by the following equation:

$$B_{\text{enc}} = \frac{A_{\text{enc}}}{1 - \bar{\alpha}_{\text{enc}}} \quad (5)$$

where A_{enc} = equivalent enclosure sound absorption area, m^2 ; $A_{\text{enc}} = \bar{\alpha}_{\text{enc}} S_{\text{enc}}$, m^2

$\bar{\alpha}_{\text{enc}}$ = coefficient of average sound absorption under the enclosure

S_{enc} = area of the enclosure structural panel surfaces through which sound penetrates, m^2

$S_{\text{enc},i}$ = area of the i th enclosure panel, m^2

m = number of enclosure panels

$SI_{\text{enc},i}$ = sound isolation of the i th enclosure panel, dB

$t_{\text{enc},i}$ = addition to the enclosure panel sound isolation depending on panel arrangement relative to the specific point, dB

R_{enc} = average distance from the enclosure to the receiver (specific point), m

x = numerical correction equals to 5 dB if $\Omega = \pi$, or to 8 dB if $\Omega = 2\pi$, or to 11 dB if $\Omega = 4\pi$ (Ω is the noise source spatial angle of sound radiation; it is equal to 4π when radiation is to the whole space, 2π when radiation is to the half space, and π for the quarter space)

The exhaust noise contribution into the exterior sound field is estimated by the following equation¹:

$$L_{\text{exh}} = L_{W_{\text{exh}}} - 20 \log R_{\text{exh}} + DI_{\text{exh}} - x \quad \text{dB}, \quad (6)$$

where $L_{W_{\text{exh}}}$ = sound power of the exhaust, dB

R_{exh} = average distance from the exhaust pipe to the specific point, m

DI_{exh} = exhaust direction index, dB

x = numerical correction described in Eq. (4)

The intake noise contribution is determined analogous to the exhaust noise component. The track noise contribution to the exterior sound field is calculated as follows¹:

$$L_{\text{tr}} = L_{W_{\text{tr}}} - 10 \log R_{\text{tr}} - x \quad \text{dB} \quad (7)$$

$L_{W_{\text{tr}}}$ = sound power emitted by tracks, dB

R_{tr} = average distance from the tracks to the receiver (specific point) of the exterior field, m

x = numerical correction described in Eq. (4)

Predicted tracked dozer noise contributions propagating to the receiver (specific point) located in the exterior sound field by various paths (in terms of A-weighted sound pressure levels, dB) are presented in the Fig. 3.

Analysis of the obtained results shows that intake noise does not affect exterior noise field, the contribution of track noise at medium and high frequencies is comparable with the contribution of the engine

Figure 3 Predicted results of noise level source contributions penetrating by different paths into the exterior sound field of a tracked dozer (spectrum data): (1) engine compartment noise contribution, (2) intake noise contribution, (3) track noise contribution, (4) exhaust noise contribution, and (5) predicted total exterior noise.

compartment noise propagating through the enclosure. Low-frequency exterior noise is mostly formed by exhaust contribution. In the example under consideration the following paths of exterior noise reduction are formulated: attenuation of the track noise (e.g., with the help of acoustical baffles) and decrease of engine body noise (by an increase of enclosure panels' sound isolation, by closing of openings and slots, and by using of sound absorption lining within the enclosure).

7 EXTERIOR NOISE REDUCTION MEANS AND METHODS

7.1 Classification

Reduction of exterior noise emitted by off-road vehicles and construction equipment may be provided at the noise source or at the noise propagation path.^{1,9} Main means of exterior noise reduction are the following: mufflers for aerodynamic (intake and exhaust) noise, sound-proofed enclosures (for reduction of engine body and fan noise), and acoustical baffles (for noise reduction in the source or to be used as additional noise reduction elements in sound-proofed enclosures). Effectiveness of the above-mentioned means depends on the noise source predominance.

For the first group of vehicles (specified in Section 4 of this chapter) decreasing the rotation velocity provides up to 3 dB to 4 dB of exterior A-weighted sound pressure level reduction, improvement of sound-proofed enclosure design may provide up to 4 dB to 5 dB of exterior noise reduction, and using of sound-absorbing materials within a sound-proofed enclosure yields reduction of exterior noise by 2 dB to 3 dB.

For the second group of vehicles isolation of tracks by application of acoustical baffles leads to the exterior A-weighted sound pressure level reduction by 3 dB to 5 dB, and the acoustical shield mounted on vibrating

roller may reduce exterior noise by 4 dB to 6 dB. Noise reduction by means of muffler application may reach 1 dB to 5 dB and depends on muffler effectiveness and on contributions of other noise sources.

7.2 Sound-Proofed Enclosures

The application of sound-proofed enclosures at the main noise source of off-road vehicles, the power plant, is a widely used technique of noise and vibration control in vehicles.

Enclosure effectiveness is determined by a number of factors: enclosure shape and size, stiffness of the shielding parts, area of the air holes and paths, average sound absorption coefficient, shielding devices for sound insulation, the damping of the enclosure parts, and so forth.

Extremely tight-fitting enclosures, providing effective sound insulation, result in a considerable air temperature rise within the enclosures that, in turn, may cause damage to or loss of performance of the power plant.

The major problem to be solved first is to provide normal heat transfer within the enclosure. This depends on the enclosure type, the total heat conductivity of enclosure walls, weather conditions, and the air temperature difference between the inside and the outside of the enclosure.

Enclosure tightness must provide necessary sound-proofing and at the same time produce no ill effects on the heat transfer from surfaces inside the enclosure. Being a universal technique to reduce noise in vehicles, an enclosure involves the addition of components to lower the propagation of airborne noise, structure-borne noise, and heat.

Enclosure walls, sound-reflecting baffles in the engine space, noise mufflers, packing units, and gaskets constitute the methods that can be used to reduce the airborne noise. Vibration isolation of the enclosed power plant and its enclosure, the vibration-absorbing enclosure wall components, the vibration-isolating packings and gaskets, the vibration dampers, antivibrators, and vibration-blocking masses hinder the structure-borne noise propagation.

The characteristic features of the vehicle engine enclosure are the following:

- Small air gap in the enclosure engine space when compared to the maximum enclosure dimensions
- Increased heat transfer into the enclosed engine airspace
- The passage of numerous engine piping systems and electric cables through the power plant enclosed space
- A number of openings, ventilation channels, and inspection windows necessary for the engine maintenance

Metal boards, transparent plastics, and sandwich (multilayer) constructions may be considered as basic construction materials for enclosure walls and surfaces.

Metal enclosures may be structural reinforced-frame constructions or structural non-reinforced-frame constructions, sectional and nonsectional, and two-wall or one-wall constructions. They usually have rectangular shape. Aluminum alloy is a preferable material for metal enclosures because this material is easily processed, has low density, and good heat reflection characteristics.

Enclosures from glass plastics in most cases are made as one-wall constructions and may have varied configurations. They are characterized by high values of sound insulation and resistance to corrosion. Application of transparent plastics reduces the metal content of an enclosure on average by 30 to 35% without degradation of structural strength or durability.

The outer layer of the sandwich (multilayer) type of construction materials consist of metal, plastics, and glass-plastics. Inner layer of sandwich-type constructions are usually made from vibration absorption material.

Inner surfaces of enclosures, as a rule, contain sound absorption and vibration absorption layers. A protection layer may also be used at the inner enclosure surface if necessary. A protection layer (a sound transparent film or a thin protection metal board) is used to prevent sound absorption material degradation caused by interference with oil, humidity, airflows, and other factors.

Sound-absorbing materials (SAM) have been found to be very useful in noise control of enclosures. Capacious fibrous and foam-type polymer materials are used as sound absorption materials in enclosures. Fibrous materials are characterized by higher sound absorption than foam-type polymer materials.

Vibration absorption coatings (VAC) are used to reduce spreading of oscillations emitted by construction elements of enclosures by means of transformation of oscillation energy into heat. Mastics, thin layers, and their combinations are used as vibration absorption coatings.

For instance, forced VAC are usually presented as combinations of dissipate layers of viscous elastic material and a thin (forced) metal layer. Shift deformation appears in the dissipate layer during bending of the construction. Vibration absorption happens in the coating due to these processes and due to material features. Various types of rubber, mastics, and other materials are used as the viscous elastic material for absorption of vibration.

Soft vibration absorption coatings consisting of a viscous elastic layer with low dynamic modulus of transverse elasticity or (and) by means of the air gap inclusions in the mastic massive cause increase of material compression ability. Mastic coating increases sound insulation of the damped wall of the enclosure by 1 dB to 2 dB in the medium and low frequencies and by 3 dB to 8 dB at the high-frequency range.

Adhesive thermos reactive glue or rigid vibration absorption coatings in the form of rigid plastics placed on the vibrating surfaces are mounted at one side of thin bitumen layers, which are used for vibration

absorption coatings. Deformation of this layer occurs when the layer is compressed or stretched.

Sound transparent films or thin protection metal boards (thickness less than 1 mm) attached to the inner enclosure surfaces may also be used as vibration protection materials. Most effective protection metal boards are made from aluminum alloys with perforation. Films covering the sound-absorbing materials reduce the coating sound absorption coefficient in the high-frequency range, thus resulting in some decrease of the enclosure effectiveness. At the same time film influence on sound absorption coefficient in the low-frequency range is negligible. Quite a different situation is observed for enclosures characterized by the presence of the enclosure underneath the opening. Their acoustical effectiveness is affected by the use of the protecting films only to a very small extent. A protecting metal board with a high-grade enclosure seal may be considered as an additional sound and heat radiation filter within the enclosure.

Acoustical effectiveness of a sound-proofed enclosure depends on the area of the SAM coating. With a coating of 15% of the enclosure inner protecting surfaces and a high degree of sealing, enclosure efficiency increases by 5 dB to 10 dB in the 125 to 8000 Hz frequency range. If the coating area is increased to 50%, an additional increase in efficiency of 4 dB to 6 dB is obtained, and a coating area of 100% increases the efficiency a further 7 dB to 13 dB, especially at the high-frequency range of 2000 to 8000 Hz (Fig. 4). Further increase of area of sound absorption coating also causes some increase of enclosure efficiency but not so significant. Such character of dependence of SAM area on the enclosure efficiency is confirmed only for closed enclosures (without an enclosure underneath the opening). The presence of an enclosure underneath the opening, ventilation channels, technological openings, slots, and the like influence sound distribution within the enclosure and change average sound absorption of the enclosure. These features yield changing

of dependence between the enclosure efficiency and sound absorption coating area.

One of the main factors that negatively influence the enclosure effectiveness is the necessity of having ventilation channels or the presence of badly sealed holes in the enclosure. The leading part is played by the size and shape of the channels (holes, openings, slots). Depending on the relationship between the wavelength of the incident sound and the size of the hole or the slot width, the enclosure acoustical effectiveness with one and the same ventilation channel area may vary throughout a considerable range.

The substitution of a single-wall enclosure by a double-wall permits increase in the total surface density by more than twice (up to a value of 10 to 15 kg/m²), which makes it possible to increase the enclosure acoustical effectiveness by 7 dB to 13 dB in the whole frequency range. But if there are unprotected ventilation channels in the double-wall enclosure structure, its effectiveness becomes 5 dB to 12 dB lower, and it approaches the single-wall enclosure effectiveness.

Acoustical effectiveness of a sealed double-wall enclosure without a sound-absorbing coating is equal to that of a single-wall coated enclosure with exception of the low-frequency region in which the acoustical effectiveness of the double-wall enclosure is higher. Double-wall enclosures may be used for sound isolation of low-speed power plants. Application of sound-absorbing coatings increases the double-wall enclosure acoustical effectiveness in the whole frequency range, and the effectiveness at high frequencies can exceed 40 dB to 50 dB.¹

There is certain dependence between the enclosure acoustical effectiveness and its shape. It is found that enclosure sound insulation increases at low frequencies is achieved with the reduction in the first resonance frequency of the enclosure due to the increase in the enclosure structure mechanical stiffness. This may be achieved by making the enclosure shielding structures with cylindrical or spherical shapes or by increasing the distance between the enclosure shielding surfaces and the power plant. The acoustical effectiveness of a spherically or hemispherically shaped enclosure at low frequencies is by 10 dB to 30 dB higher than of flat-walled ones with the same volume.

The spherical, hemispherical, or cylindrical enclosure shape in combination with an enclosure inner surface sound-absorbing coating and with an outer vibration damping coating permits an increase in sound insulation effect throughout the whole frequency range. At low frequencies, due to the greater stiffness of the enclosure, the sound insulation increases because of the resonance frequency shift toward the medium-frequency region, where the vibration damping coating effectiveness is high. In the medium-frequency range the vibration damping coating effect is equivalent to an enclosure dynamic stiffness increase. In the high-frequency region the enclosure sound insulation increases both due to the vibration damping coating, which increases the energy loss because of the enclosure shell vibration, and due to the use of a sound-absorbing coating.

Figure 4 Dependence of the acoustical effectiveness of a coated enclosure on the area of sound-absorbing material (SAM): (1) area of SAM, 0%; (2) area of SAM, 20%; (3) area of SAM, 40%; (4) area of SAM, 60%; (5) area of SAM, 80%; and (6) area of SAM, 100%.

The relationship between the enclosure sound insulation of effectiveness and its dimensions is almost unpredictable: With increase of enclosure size and therefore with increase of the enclosed volume, the enclosure radiation surface area increases but at the same time the sound intensity on the enclosure inner walls decreases.

7.3 Engine Exhaust Noise Mufflers

Engine intake and exhaust noise mufflers are the significant noise control measures and play the most important role in the exterior noise reduction of noise sources with aerodynamic genesis. A-weighted sound pressure levels emitted by nonmuffled exhaust reaches 115 dB to 130 dB and may exceed noise of all other sources by 10 times. A-weighted sound pressure level of a nonmuffled intake is lower but also may reach 100 dB to 110 dB. Thus engine intake and exhaust noise mufflers are compulsory mounted on exhaust and intake systems of a vehicle engine.

Muffler functioning bases on two principles of sound intensity reduction by absorption or reflection (acoustical filters) and by decreasing the gas flow energy in the exhaust chamber (temperature, energy, gas flow velocity and pressure, smoothing of its pulsations) that leads to decreasing of sound energy effectiveness near the gas exits to the atmosphere.

The common classification of mufflers divides them into three classes in accordance with the principle of their operation:

- **Reactive** where the sound reflection takes place in the elements of expansion (contraction) in expansion chamber

- **Absorbing** where the sound energy transforms into the heat in soft fibrous coatings
- **Combined** which combines two preceding principles

Mufflers as suppressors of the gas flow energy used in gas exhaust channels consist of the following elements: expansion chambers, perforated pipes and partitions connecting pipes, solid partitions and others. Such elements provide the expansion of gas flow, turning and smoothing what results in energy losses of the flow and noise reduction. Figure 5 shows some mufflers used in off-road vehicles and in movable compressors and their main elements.

Acoustical mufflers-filters are usually used for intake systems and may be either reactive (expansion chamber) or absorbing (chamber partly lined with a sound-absorbing material).

The influence of some basic muffler elements on the acoustical effectiveness of the muffler is shown in Fig. 6. From the presented results the extension of muffler volume increases its effectiveness at low frequencies.

Bend of the gas flow yields an increase of the muffler effectiveness in the medium- and high-frequency regions. Application of perforation in mufflers provides noise reduction in the wide frequency range. Use of sound absorption yields the effectiveness increase at the medium and high frequencies.¹

Installation of the muffler in a gas channel provides increasing of pressure loss. For instance, pressure losses of 3000 to 5000 Pa (i.e., the common value for many exhaust noise mufflers) causes the fall of the

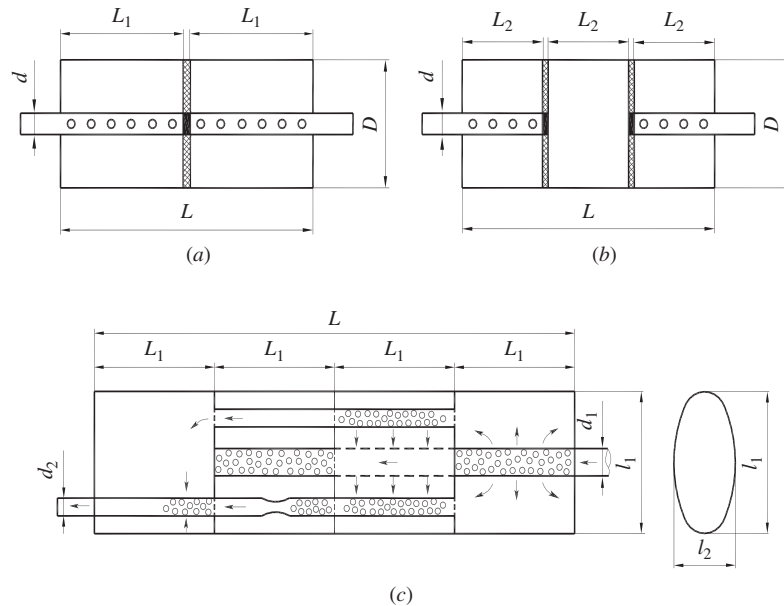

Figure 5 Exhaust noise mufflers used for noise reduction in off-road vehicles and in movable compressors: (a) two-chamber reactive muffler, (b) three-chamber reactive muffler, and (c) four-chamber muffler.

Figure 6 Noise spectra of muffler effectiveness depending on muffler construction: (1) empty chamber (a basic design for further comparison and analysis), (2) empty chamber of two times higher volume than the basic model muffler, (3) three-chamber muffler with two perforated partitions that volume is equal to the basic muffler, (4) empty chamber lined with sound-absorbing material, and (5) single-chamber muffler with right bend at the gas flow at the muffler outlet.

engine power by 1 to 1.5%. Thus, in most cases, design of an effective muffler is the compromise between providing necessary noise reduction and obtaining required pressure loss. Construction performance of modern mufflers tends to design complication and muffler enlargement. According to the newest exterior noise limitations, muffler structures have become more complicated because of the growth of the number of chambers, by introducing the elements provided multiple bends of gas flow, by using elements with large perforated areas, or with sound absorption lining.

An example of a muffler providing high effectiveness (up to 40 dB) and relatively low pressure loss (lower than 7000 Pa) is shown in Fig. 7. The feature of this muffler is the elliptical shape of the muffler body. The muffler consists of several internal pipes and partitions providing gas flow division into several jets with subsequent interference and extension of gas path through the muffler. Inlet flow turn and outlet sound-absorbing chamber are designed in the muffler. Described construction of the muffler allows providing high effectiveness of the muffler with minimal loss of the engine power. This muffler may be exploiting for the internal combustion engine with the power of 40 to 150 hp. Particular parameters of this muffler used in a movable compressor are the following: big axis of the ellipse is 300 mm; small axis of the ellipse is 170 mm; pressure loss is 500 mm H₂O; and obtained acoustical effectiveness is 38 dB (23 dB to 52 dB in the frequency range of 63 to 8000 Hz). Details of effectiveness of the engine exhaust muffler are given in the Table 6.¹⁰

Active mufflers located in the gas exhaust systems are also used nowadays for exterior noise reduction. Such systems provide effectiveness of 5 dB to 15 dB at some low frequencies (lower than 200 Hz). Active mufflers are characterized by the presence of an artificial noise signal generated within the exhaust pipe in antiphase to the noise emitted by the vehicle exhaust system. Noise reduction is obtained due to the interference of two signals.

7.4 Acoustical Baffles

Acoustical baffles are the supporting sound-proofed constructions that may be installed near local noise

Figure 7 Exhaust noise muffler for a movable compressor: (1) muffler body, (2) cylindrical tumbler, (3) central perforated pipe, (4) inlet pipe, (5) outlet pipe, (6) elliptical partition, (7) solid partition, (8) partition, (9) gas channels, (10) expansion chamber, (11) solid bottom, (12) perforated partition, (13) vibration-damping material, (14) solid partition, and (15) sound-absorption material.

Table 6 Effectiveness of Exhaust Noise Muffler

Descriptor	Sound Pressure Levels and Enclosure Effectiveness (dB) in Octave Frequency Bands (Hz)							
	63	125	250	500	1000	2000	4000	8000
Exhaust without muffler	129	124	128	125	122	121	129	123
Exhaust with muffler	106	98	94	84	86	84	81	71
Effectiveness of the muffler	23	26	34	41	36	37	48	52

sources of the off-road vehicles (e.g., near the tracks, transmissions, hydraulic system, and others). Acoustical baffles may be used as noise protection in sound-proofed enclosures, for example, to partially cover an opening or an aperture in a sound-proofed enclosure. Acoustical baffles may be produced in various shapes (Fig. 8).¹¹

Baffles may be rigid (metal, as a rule) or soft. It is necessary to use sound absorption for increasing acoustical baffle effectiveness (Fig. 9).¹¹

Acoustical baffles allow achieving up to 5 dB to 10 dB reduction of the exterior A-weighted sound pressure levels emitted by local noise sources. Baffles are expected to become a widely used measure for exterior noise reduction of the off-road vehicles.

8 EXAMPLES OF EXTERIOR NOISE REDUCTION USED IN OFF-ROAD VEHICLES AND CONSTRUCTION EQUIPMENT

Let us consider two noise reduction schemes used to decrease exterior noise emitted by a movable compressor. The first example describes a movable compressor with an electric motor drive (Fig. 10). A steel sound-proofed enclosure (1) of 1 mm thickness lined with sound-absorbing material (2) of 30 mm thickness was used for exterior noise reduction. The enclosure is divided into two chambers—one is for an engine (3) and another is for a compressor (4). Each chamber has an independent air intake system. The compressor intake filter (5) is covered with a light hood to avoid heating. This hood performs functions of an enclosure muffler (6) and the air duct at the same time. The heated air is released

Figure 10 Sound-proofed movable compressor with an electric motor drive: (1) sound-proofed enclosure, (2) sound-absorbing material, (3) electric motor, (4) compressor, (5) intake filter, (6) enclosure muffler, (7) exhaust opening, (8) enclosure roof, (9) acoustical baffles.

Figure 11 Sound-proofed movable compressor with a diesel engine: (1) compressor, (2) diesel engine, (3) sound-proofed enclosure, (4) engine exhaust muffler, (5) vibration isolators, (6) intake filter, (7) fan, (8) cooler, (9) frame, (10) exhaust slots, (11) acoustical baffles, (12) intake chamber, (13) exhaust chamber, (14) enclosure roof, (15) duct, (16) sound absorption coating.

through an exhaust opening (7) in the enclosure roof (8). Ventilation openings are protected with acoustical baffles (9). Described enclosure provides A-weighted sound pressure level reduction of 8 dB, and sound pressure level reduction of 5 dB to 11 dB in the frequency range of 500 to 8000 Hz.

Noise reduction equipment for a movable compressor (1) with a diesel engine (2) consists of a sound-proofed enclosure (3), engine exhaust muffler (4), and vibration isolators (5) for the engine-compressor unit (Fig. 11). The sound-proofed enclosure protects the engine with a turbofan, intake filter (6), fan (7), and cooler (8) installed on the frame (9). The enclosure has intake and exhaust slots (10) on its end and side panels. Inside the compressor enclosure, baffles, partitions, and an engine hood are installed. The wall faces of the main hood, partitions, and baffles (11) form the intake (12) and exhaust (13) chambers. On the main

enclosure of the roof (14), a duct (15) with an opening is installed. It is connected to the outer enclosure. An exhaust gas muffler is placed under the duct. Enclosure, partitions, and baffles are lined with a sound-absorbing material (16). The engine-compressor unit is mounted to the frame through the vibration isolators of the AKCC-160M type. The enclosure is made of 1.5-mm-thick steel. Elastic incombustible polyurethane of PPU-ET type is chosen as a sound-absorbing coating (with a layer of 40 mm thickness). Described noise control measures reduce sound pressure level by 6 dB to 17 dB in the frequency range of 250 to 8000 Hz.

1 INTRODUCTION

Community noise sources, such as transportation modes, recreational activities, and commercial and industrial developments, can impact residential areas negatively. Environmental noise impact assessments provide a mechanism to investigate the balance between the negative noise impacts of a proposed development project versus the benefits that that development project is expected to bring to the community. Existing community noise exposure guidelines are consulted when preparing the assessments. These are based on the premise that there is a level of noise that is acceptable to protect most humans, animals, and structures. If this level is likely to be exceeded by a proposed development, appropriate mitigation measures need to be selected with due consideration of cost and technical feasibility. The mitigated noise impact is assessed for acceptability to the potentially affected community as well as the benefit of the development to the community as a whole. In this chapter the terms *community noise* and *environmental noise* are used interchangeably.

2 ENVIRONMENTAL NOISE DESCRIPTORS

The definition of environmental noise given in the recent European Commission Environmental Noise Directive¹ is: "unwanted or harmful sound created by human activity outdoors, including noise emitted by means of transport and from industrial sites or industrial buildings."

Quantitative descriptors for environmental noise are generally based on the A-weighted decibel scale. The A-weighting is essentially a frequency filter that has a similar response to that of human hearing. As environmental noise is rarely constant in level, this time variation must be taken into consideration to provide a representative noise descriptor. A variety of such derived noise descriptors have been developed that incorporate time averaging of the sound pressure levels or integration of the energy within a sound over a defined period. Commonly used descriptors include:

- **Percentile Value, L_{An}** The A-weighted level exceeded for a percentage of a nominated time

period. The most commonly used are the L_{A10} , the level exceeded for 10% of the time period and so representative of the higher noise levels, and the L_{A90} , the level exceeded for 90% of the time period and considered representative of the background noise levels.

- **Equivalent Energy Level L_{Aeq}** The A-weighted sound pressure level for a continuous steady sound that has the same energy as the time-varying sound over the same time period. The L_{Aeq} is the basis for a number of derived descriptors discussed below.
- **Maximum Noise Level, L_{Amax}** The maximum noise level during the time period and often used as a criterion in conjunction with L_{Aeq} or L_{A10} to limit the highest noise levels in the noise.
- **Sound Exposure Level (SEL)** The noise level for a sound over a defined time period, such as 1s, that would have the same energy as the noise from a single event like a helicopter flyover or a train passby.
- **Perceived Noise Level (PNL)** The level of a sound that is considered to be equally noisy. It is calculated from the one-third octave band data.
- **Peak Noise Level, L_{Cpeak}** The peak C-weighted sound pressure level for impulse sound such as explosive noise. Note this environmental noise descriptor is not based on the A-weighting but is based on the C frequency weighting.

A number of derived noise descriptors are used for the assessment of noise impacts. The common ones include:

- **$L_{A10,18h}$** The average of the hourly L_{A10} values between 06:00 and 24:00 and used for the assessment of noise from road traffic.
- **$L_{Aeq,Nh}$** Average of L_{Aeq} over a defined number of hours such as 24 h, 9 h over a night, 15 h over a day, 1 h over a day, and so on, and used for wide range of environmental noises.

- **LDEN** The average of L_{Aeq} over the day with an adjustment to allow for the additional annoyance during the defined evening and night periods. The day period is 12 h and normally from 06:00 to 18:00, the evening 4 h normally from 18:00 to 22:00 with an adjustment of +5 dB, and the night 8 h with an adjustment of +10 dB. This derived descriptor is planned to be used in implementation of the new European Commission (EC) Directive on Environmental Noise.¹ The length of each period is given in hours, but the clock times can be changed to suit the lifestyle of the country.
- **DNL** The average of L_{Aeq} over the day with an adjustment of 10 dB to allow for the additional disturbances during the defined night period. DNL is commonly used in the United States. A comparison between the L_{DN} and L_{DEN} is provided in Miedema and Oudshoorn.² According to these authors, for specific types of noise the agreement is aircraft LDEN = DNL + 0.6, road traffic LDEN = DNL + 0.2, and railway LDEN = DNL.

As there are a large variety of descriptors for environmental noise, it is vital that the descriptor used for a criterion in regulations and guidelines be clearly stated to avoid any ambiguity. These details also need to be considered when comparing noise effects research findings and noise exposure criteria from various countries to ensure the validity of the comparison.

When there are particular frequency characteristics in the noise, such as from music or motor sports, it may be necessary to incorporate criteria based on the noise levels in particular frequency bands, in addition to the overall A-weighted level. These criteria generally use the L_{eq} descriptor.

3 REACTIONS TO ENVIRONMENTAL NOISE

The term environmental noise describes the noise generated by all the aspects of our society as it impinges on the usual activities of our daily lives, excluding occupational noise. It is only rarely that the level of environmental noise would be sufficient to produce permanent hearing damage. Transportation is a widespread source of noise and is heard to some extent by the majority of those living in urbanized areas and some of those living in rural areas. Other forms of environmental noise are related to activities associated with industry and mining, with commercial activities, with recreation, and with neighbors.

Annoyance, speech interference, and sleep disturbance are considered to be the main effects of environmental noise. Studies on nonauditory physiological health effects of those exposed to higher levels of environmental noise have shown some association with hypertension, cardiovascular, and digestive problems, for example, see the review by Stansfield and Lercher.³ However, there are many confounding factors that can effect these reactions, and there is currently no clear relationship between a noise descriptor and particular physiological effects.

4 DOSE-RESPONSE RELATIONSHIPS

Important factors that lead to reactions to noise such as disturbance and annoyance include the noise level and character, the duration, the time at which it is occurring, and the activity of the person at that time. The difficulties in determining a quantitative assessment of noise annoyance are discussed in more detail in Chapter 25. There have been extensive studies (see discussions by Fields^{4,5} and by Finegold and Finegold⁶) aimed at determining the relationship between some form of noise descriptor and reaction to environmental noise. These social surveys have typically led to dose-response relationships based on some form of quantitative descriptor for the noise and the percentage highly annoyed (%HA). The majority of these surveys have focused on reactions to transportation noise sources.

The first such curve to gain wide application was developed by Schultz.⁷ In subsequent decades more surveys were undertaken and the older work reanalyzed, for example, by Fidell et al.⁸ and Finegold et al.⁹ It became apparent that there were differences in the relationships between the reactions to different types of transportation noise.⁹ However, as there was not a clear 5-dB difference between the curves, the combined curve shown in Fig. 1 was adopted in an American National Standards Institute (ANSI) standard.¹⁰ Since then, a more comprehensive database of community annoyance data has been compiled by The Netherlands Organisation for Applied Scientific Research (TNO) Division of Prevention and Health. Analysis of these data by TNO^{2,11,12} led to separate dose-response relationships for noise from aircraft, road traffic, and railways, as shown in Figure 2. However, there is not universal acceptance of these three curves and the limitations have been discussed by Finegold,⁶ concluding that there needs to be "more open dialog and debate concerning technical issues related to community annoyance research, along with freely sharing of data between researchers."

Both the International Organization for Standardization (ISO) and the ANSI are reconsidering the issue of the appropriate exposure-response relationship to

Figure 1 Dose annoyance curve. (From Finegold et al.⁹)

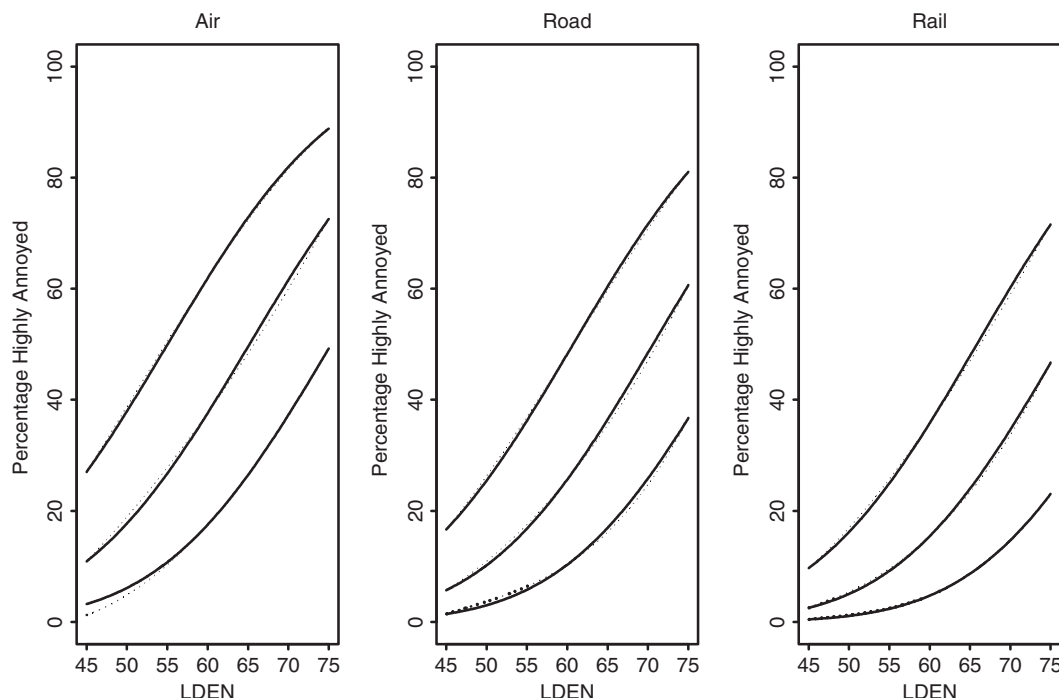

Figure 2 Dose annoyance curves. (From Miedema and Oudshoorn.²⁾)

use in their respective environmental noise standards and are reviewing a number of published curves. The recent revision of ISO 1996–1¹³ recommends reverting to use of the original Schultz⁷ community annoyance curve, but with adjustments for the type of noise source (road traffic, aircraft, and railways), special characteristics of the sound, and the time of day. In the United States, ANSI is considering making the same change, rather than the current use of the Finegold et al.⁹ curve. In contrast, it appears that the European Commission will adopt the three separate curves developed by TNO. The World Health Organization has not advocated for adoption of any particular exposure–response curve.

4.1 Sleep Disturbance

The most common metrics for assessing the impacts of community noise, such as DNL, already contain a strong 10-dB penalty for nighttime noises, and community noise exposure policies typically do not include separate criteria for sleep disturbance. However, there are circumstances where a separate analysis of the impacts of nighttime noise is warranted. There have been extensive studies of sleep disturbance using subjects sleeping in their homes and sleeping under laboratory conditions. The results of the studies are highly variable but, similar to the findings on community annoyance, there is clearly an increase in sleep disturbance with noise level. This topic is examined in detail in Chapter 24 and exposure–response relationships for sleep disturbance

may be found there. The World Health Organization (WHO)¹⁴ has recommended that nighttime indoor sound pressure levels should not exceed approximately 45 dB L_{Amax} more than 10 to 15 times per night. For intermittent events similar to aircraft overflights, with an effective duration of 10 to 30 s, this corresponds to indoor A-weighted SEL values of 55 dB to 60 dB. According to WHO, either L_{Amax} or SEL may be used if the noise is not continuous. For total night exposure, a criterion of 30 dB $L_{Aeq,8h}$ was recommended for use in combination with the single-event criterion (L_{Amax} or SEL). It needs to be pointed out, however, that the criteria recommended by WHO are long-term targets and do not take into consideration the cost or technical feasibility of meeting their recommended ideal maximum exposure levels. WHO intended that these criteria be used as part of a noise management decision-making process, for which environmental noise impact analysis is the central issue.

4.2 Speech Interference

Speech interference is also an important part of the overall assessment of annoyance. For specific situations where the level of environmental noise is high, speech interference is possible inside buildings, such as schools or offices near busy roads or airports. There are national and international standard test procedures to determine quantitative measures of speech interference that have been designed for room acoustics (see Chapter 106 for more details of these methods).

5 METHODS FOR ASSESSMENT OF NOISE IMPACT

5.1 Assessment by Comparison with Background Noise Levels

Assessment of the acceptability of an environmental noise is necessary to judge if complaints about an existing noise source are justified or if a proposed development can proceed with or without mitigation measures. One approach involves comparison with background noise levels and is more applicable for assessment of industrial, commercial, or neighbor noise than for transportation noise. The aim is to limit the intrusiveness of the noise. This approach to assessment requires measurement of the noise level in the area before the proposed development, or if it is in response to a complaint, with the noise considered to be offensive turned off. If it is not possible to turn the noise source off, the background noise measurements can be made in a similar type of area. The background noise is usually measured in terms of L_{A90} , the A-weighted noise level exceeded for at least 90% of the time period. The background noise can vary during different times of the day so the measurements must be made during the time the noise may be considered to be annoying. The measurement of the background noise may need to be over a number of days in which case the 90% value of the L_{A90} can provide a good representation of the background noise level in the area.

After the background level of noise is determined, then either the noise from the existing source is measured or noise from the proposed development is predicted. This noise is generally either in terms of L_{A10} , the A-weighted noise level exceeded for 10% of the time period, or L_{Aeq} , the A-weighted equivalent noise level. Adjustments are then made to the noise level to allow for the additional annoyance because of the character of the noise. Objective and subjective methods for determining these adjustments are given in ISO 1996, Part 2.^{13,15} However, it is essential to check local regulations as they may differ from the guidance in ISO 1996. Typically, values for adjustments to the measured noise levels are +5 dB for a prominent tonal component and for an impulse or impact noise. It is also common to allow for the criterion at the receptor to be increased when the comparison is made with a single event in any 24 h. This increase in criterion is related to the length of time of the event, and for an event with less than 1.5 min duration can be as high as 20 dB during daytime or 10 dB during nighttime.

The adjusted measured, or predicted, noise level is compared with the background noise level with an excess of +5 dB considered acceptable. This is based on the assumption that such small increases in noise level are not likely to cause a long-term significant increase in annoyance. A 5-dB increase is also often used to determine whether a full Environmental Impact Statement needs to be prepared. A general guide to the expected reactions to noise intrusion is given in Table 1.

The concept of assessment by comparison with background noise level is easy for the community to understand, but there are a number of disadvantages.

Table 1 Guide to Reactions to Different Levels of Noise Intrusion for A-weighted Sound Pressure Levels

Noise Intrusion	Likely Reaction
0–5 dB	Marginal
5–15 dB	Great concern
15–20 dB	Serious concern
20–25 dB	Extreme action

Source: Based on data from the U.S. Environmental Protection Agency¹⁶ and the earlier report of Eldred.¹⁷

Background noise levels vary from day to day, so long-term noise monitoring is required to obtain a consistent value. Most modern measurement instruments allow for pausing of the data collection when extraneous noise is present, but often decisions need to be made “on the spot” if noise should be considered as part of the background noise in the area. Limits for the total noise must be established to avoid gradually increasing or “creeping” background noise as each new source is introduced. The assessment method does not encourage the overall reduction in environmental noise.

5.2 Assessment of Environmental Noise by Comparison with a Specified Criterion Level

This method involves defining criteria for acceptable noise levels in an area with the aim of maintaining the amenity of the environment. The estimated noise levels from proposed developments or the noise levels from current activities should not exceed these criteria. A number of factors are taken into consideration by the authority when selecting these criteria. Criteria often vary for the type of area and time of day. The types of activities plus the transportation such as roadways, railways, and airports all contribute to the overall ambient noise that constitutes a city area. In rural areas the expectations are for a quieter environment. Similarly higher noise levels during the day are more acceptable than during the night when they may cause sleep disturbance. The findings from surveys of noise annoyance are also taken into consideration but, as discussed above, these do not give a definite level that can be considered as acceptable to all.

This method has been commonly used for assessment of transportation noise but is also applicable for general environmental noise. There is an increasing trend to include an adjustment to take into consideration the increased annoyance to noise during the nighttime and the evening. Options for such criteria include:

- Different criteria for the average over specific time periods during the 24 h, that is, daytime, evening, and nighttime
- Average over a relevant time period for the adjacent land uses, that is, during the school day or the office hours
- Level that must not be exceeded during any one hour, or shorter time if applicable, for critical spaces such as hospitals

Table 2 Guideline Values for Community Noise in Specific Environments

Specific Environment	Critical Health Effect(s)	L_{Aeq} (dB)	Time Base (h)	$L_{Amax,fast}$ (dB)
Outdoor living area	Serious annoyance, daytime and evening	55	16	—
	Moderate annoyance, daytime and evening	50	16	—
Dwelling, indoors	Speech intelligibility and moderate annoyance, daytime and evening	35	16	—
Inside bedrooms	Sleep disturbance, nighttime	30	8	45
Outside bedrooms	Sleep disturbance, window open (outdoor values)	45	8	60
School class rooms and preschools, indoors	Speech intelligibility, disturbance of information extraction, message communication	35	During class	—
Preschool bedrooms, indoors	Sleep disturbance	30	Sleeping time	45
School, playground outdoor	Annoyance (external source)	55	During play	—
Hospital, ward rooms, indoors	Sleep disturbance, nighttime	30	8	40
	Sleep disturbance, daytime and evenings	30	16	—
Hospitals, treatment rooms, indoors	Interference with rest and recovery	^a		—
Outdoors in parkland and conservation areas	Disruption of tranquility	^b		

^aAs low as practically possible.

^bExisting quiet outdoor areas should be preserved and the ratio of intruding noise to natural background sound should be kept low.

Source: Extracted from Table 4.1 in WHO Guidelines.¹⁴ The time base for the L_{Aeq} value varies as shown in the table.

- One value that is the average of the L_{Aeq} during the day and the night but with an adjustment of 10 dB added to the nighttime levels, that is, L_{DN} , as used in the United States
- One value that is the average of the L_{Aeq} during the day, the evening, and the night but with an adjustment of 5 and 10 dB, respectively, for the evening and the nighttime levels, that is, L_{DEN} , as used in the European Union (EU) directive on noise

The advantage of this method is that the criterion value is established so all involved with the assessment know what the goal is. Allowance must be made for transition areas between zones with different standards, such as a commercial area near a residential area. One management method is to apply the average of the zone criteria near to the boundary between the zones. If the existing noise level is in excess of the zone noise criterion, decisions need to be made.

5.3 Establishing Noise Exposure Criterion Levels

Studies on the reactions to environmental noise give a guide to reasonable criteria that the government authority can adopt. However, as discussed above, most of these

studies show that annoyance increases with noise level at different slopes for different types of noise, and there is no firm agreement about a level that clearly separates an acceptable from an unacceptable noise impact.

A robust dose–response relationship can give guidance to the authorities and others charged with making the decisions defining acceptable levels of noise. The WHO supported an extensive study of the available data, and the outcomes have been published for such guidance by Berglund et al.¹⁸ The guidelines for environmental noise have been extracted from the table in the WHO document and are shown in Table 2. These have quickly become acknowledged worldwide as the goals for which authorities should aim for community noise criteria.

5.4 Interpretation and Use of Noise Exposure Criterion Levels

All environmental noise impact analyses should include comparison of the noise level at the receiver location with the applicable exposure criteria. These criteria are immission levels, that is, the noise that is received at a particular location and is the cumulative noise from all the sources in the area. When the immission noise level is in excess of the criterion, the first step should be to attempt to mitigate (reduce) the

emission noise at the source. As discussed in other chapters, there are many alternatives for the reduction of the emission noise at the source. Once the maximum reduction in emission noise has been achieved, other approaches to noise control, such as use of barriers or improving the noise reduction provided by buildings, can be applied to reduce the immission noise levels to meet the criteria. Of course, environmental noise should be considered at the land-use planning stage to minimize the occurrence of inappropriate land uses. This is very important for management of environmental noise at the community level. For example, great care should be taken to consider the noise impact prior to releasing land for residential use in areas that are potentially noisy such as in the vicinity of aircraft flight paths or near industrial estates. The potential impact should not just be considered at the time of the proposed development but into the future, 5, 10, 15, or even 20 years.

In the production of any environmental impact statement it is important to identify the status of the criteria that are being used in the assessment of acceptability. The WHO criteria in Table 2 are guidelines only and as such carry no legislative power and hence are not enforceable by law. Similarly criteria listed in standards such as those produced by ISO or by individual countries are also only guidelines. It is up to each jurisdiction to introduce regulations or similar legal instruments listing criteria with which compliance is then enforceable by law. The approach to legislation varies from country to country, and the regulations can be introduced at the local government level, at the state government level, or at the federal government level.

6 ASSESSMENT OF PROPOSED DEVELOPMENTS

6.1 Environmental Noise Impact Assessment

Environmental impact assessment (EIA) is just one term that is applied to the processes of establishing the extent of all impacts on the surrounding areas of a proposed development. Other terms that essentially mean the same are environmental effects statement, review of environmental effects, and the like. For most projects there are a number of stages in the EIA process. In some cases the EIA may only be assessed by the appropriate government authorities. Commonly a draft assessment is produced and released for a public comment period during which time community discussion sessions may be organized. The final EIA should then address all of the relevant issues that have been raised during that public comment period. The magnitude of the EIA is related to the size of the proposed development. An EIA for the construction of a new runway at an airport will comprise many volumes, while an EIA for a smaller project like a residential complex may be only one slender document. Noise is one component that must be considered as part of an EIA.

The basic elements for the first part of the noise assessment in an EIA include:

- Identification of all the noise-producing elements in the proposal
- Identification of all the noise-sensitive areas that could be affected by the proposal both currently and into the future, say 15 to 20 years
- Statement of the applicable criteria in the surrounding areas
- Estimation of the noise immission levels for all the noise-sensitive locations
- Comparison with the applicable criteria and determination of any excess

If there is an excess, the next steps are:

- Identification of cost-effective mitigation measures
- Comparison of the mitigated noise immission levels with the criteria

For equity, the onus of responsibility for the mitigation measures should rest with the proponent of the proposed development. Thus, a new or upgraded road development through a suburban area should include mitigation to meet the criteria as part of the road project. On the other hand, if land near an existing major road or an industry is rezoned from broad acre to residential, the responsibilities for mitigation should lie with the residential developer. The responsibility for mitigation can become more complex when there is not a clear rezoning but simply a change of use. For example, a commercial complex may include an entertainment venue that has been used only during the day and causing no problem to the surrounding residences. A change of tenant, still within the property zone allowances, may lead to a change of operations that may cause annoyance to the residents. If assessment on the basis of the criteria for the nature of the area and the time of day shows an excess, then the responsibility for mitigation is with the new leasee. However, if there is no excess, then any mitigation needs to be undertaken by the residents.

It is reasonable to consider the cost effectiveness of mitigation measures since complete mitigation of the noise may be beyond the current technical capabilities or may be prohibitively expensive for the proponent.

After this stage there is sufficient information for a community consultation period, which is aimed at advising members of the community and seeking their opinions. For smaller projects it may be sufficient to advise the community that the documentation is available for inspection on the Internet or at government offices. For larger and for controversial proposals it may be necessary to arrange for public displays, information sessions, and discussion groups.

If the noise criteria are met with mitigation measures that are acceptable to the community, a satisfactory conclusion has been achieved in terms of noise control. If either the mitigation measures are unacceptable or the mitigated noise levels are in excess of the criteria, a review of the EIA plus negotiation with the concerned community is required. Some changes to

the proposed mitigation measures to meet the community requirements may not change their effectiveness, for example, changing the material of barriers from opaque to transparent. Other changes may reduce the effectiveness of the measure, for example, reducing the height or location of a barrier wall, and negotiation will be required.

6.2 Negotiation Process

Achieving a satisfactory resolution involves the three main stakeholders—the proponent, the community, and the government authority. The economic and social benefits to the wider community need to be evaluated with regard to the undesirable noise impact for the affected proportion of the community. The proponent must be able to demonstrate that application of all the economically viable mitigation strategies has been considered. The EIA and supporting documents must provide the assessment and the evaluation in a form that can be understood by the community. An independent facilitator should assist with the negotiation to avoid accusations of bias by either the proponent or the government authority. Advances in noise simulation offer the opportunity to provide an audio demonstration of the expected noise in various areas. While this may assist the community to better understand the type of noise and the possible level, it does have some disadvantages and should be used only with caution. The inputs for the simulation model, the sound system, and the meeting venue can all affect the sound produced. There is also a possible psychological effect whereby intentionally listening to the sound produced by the simulation could lead to a different reaction than if the sound was superimposed on other sounds in a normal environment.

The basis of any agreement is that the community receives some benefits to offset the noise impact. Of course, these benefits have to comply with what is legally permitted under the jurisdiction. The benefits could be payments, improved noise insulation of the houses, improvements to the community infrastructure, and the like. Benefits could also involve a sharing of the noise impact, for example, the flight tracks for an airport could be changed so that a balance is achieved between high and low noise days. Agreement could be reached on a management control method that encouraged lower noise activities; for example, a motor sports facility or an outdoor concert venue could have an annual credit allowance whereby higher noise emission events would use more of the credits than low noise events.

It is not uncommon that there is initially not unanimous acceptance of the noise predicted from a proposed major development project. Adequate noise policies need to clearly identify the responsibilities and rights of all the involved government authorities, the local community, and the business arena for what is required for environmental noise decision making. An environmental noise impact analysis process, which would be required for all proposed major development projects to assess the expected noise impacts on the community, could be the central focus of the required

noise management program. The results of this process include decisions about acceptable noise exposure levels, noise mitigations measures, and the like. Once this agreement has been reached, it becomes binding on the community so that future new members of the community must accept the negotiated agreement. The final negotiated decisions are documented in a record of decision (ROD), and approval to proceed with the planned development project is granted, subject to the provisions of the ROD. If agreement cannot be reached between the government, the developers, and the community, a formal dispute resolution system could be used to settle the disagreements and finalize the noise-related decisions.

6.3 Interacting with the Public

It is important in the whole assessment process to provide information in a manner that can be understood by the community that is potentially affected. The various descriptors for noise are not necessarily easy for the community to understand. This is especially the case for descriptors that involve averages over long times, such as 24 h or even more. The community needs to understand that such criteria do not mean that the noise will not exceed the stated value at any time. Part of the assessment documentation should clearly identify what the variations in noise level may be yet still meet the criterion. For example, with aircraft noise assessment the documentation should show that while the operations may meet the criteria, there may also be a number of overflights for which the noise levels will exceed certain values. Work by Southgate¹⁹ on aircraft noise assessment in Australia has indicated that communities seek information and are more accepting if they consider the proponent has clearly stated all the potential impacts as well as showing that specific criteria will be met. A responsive complaint management system has also been shown to be a quite useful public interaction tool in countries such as Japan.

6.4 Monitoring and Review

Permission to proceed with the proposed development should not be the end of the process. The government authority needs to ensure that noise monitoring is undertaken so that the actual noise levels are not in excess of those estimated and that the mitigation measures are maintained and are effective. Changes to the development should trigger a review of the EIA to ensure the noise levels do not increase. Guidelines as to what are considered substantial changes need to be carefully defined by the government authority.

7 SUMMARY

Environmental impact assessment for the noise from a proposed development requires assessment of the predicted noise level at the receiver and comparison with current acceptability criteria. These criteria differ for a variety of factors including the type of receiving location, the type of area, the time of day, the type of sound source, and the like. An environmental impact assessment should show that an appropriate noise management plan has been implemented to ensure that

the criteria are met. If it is not reasonable or feasible to meet the criteria, alternatives may be available to allow the development to proceed while minimizing the impact on the surrounding areas. It is important to remember that reaction and annoyance to noise varies greatly across the community, and establishment of criteria levels is based on an acceptance that there may still be a small proportion of the community who will experience annoyance or disturbance from the noise. The environmental noise impact process, especially with its receiver-oriented (immission) perspective, is a crucial part of an effective community noise management strategy.

CHAPTER 128

INDUSTRIAL AND COMMERCIAL NOISE IN THE COMMUNITY

Dietrich Kuehner
de BAKOM
Odenthal, Germany

1 INTRODUCTION

In most industrialized countries, the legal limiting values for industrial and commercial noise are different from those for road traffic noise. There is, however, a general consensus that the annoyance produced by road traffic is very similar to that produced by industrial or commercial noise if the long-term energy equivalent sound pressure levels are the same. However, this is considered to be true only if the noise is not tonal or low frequency or impulsive in character. There have been extensive studies of this problem in the United Kingdom.

Different zoning solutions have been developed to control the noise from light and heavy industry and commercial enterprises including retail outlets, restaurants, and warehouses. Enterprises categorized as industrial are designated to specific zones that have been created for numerous reasons, of which noise is just one. With this approach, a reasonable separation of residential areas from noise-producing activities can be ensured. Similarly, commercial enterprises are also allotted to areas that may be closer to residential areas under the assumption that the emission from such areas is less. To limit the emission from such areas, specific sound power levels are introduced in relation to the size of the area. It is often necessary to carry out noise measurements in order to obtain the necessary data to establish—if necessary—a mitigation scheme.

2 INDUSTRIAL ACTIVITIES AND LOCAL COMMUNITY REACTIONS

Industrial and commercial noise can be subdivided into two categories. Into the first category falls stationary noise with small variation during day and nighttime, and into the second falls the intermittently occurring noise resulting from transport, production cycles, impulses, and the like, including truck traffic to and from an industrial area.

The stationary part is generally accepted if no single-tone components are involved up to nighttime A-weighted long-term equivalent L_{eq} levels of 48 dB. Above this level, reactions from the neighborhood are frequently observed. Similarly, a 10-dB higher value is accepted for the daytime, even if the noise is nonstationary as long as it is not impulsive or tonal.

The reaction of the community to industrial and commercial noise is very similar to that of road traffic noise of typical roads in a community. Noise resulting from superhighways seems to be more annoying at comparable levels.¹ However, if the noise is tonal or

impulsive in character, including low-frequency noise (below 90 Hz), the reaction can be severe.

The extent of the problem can be derived from a survey performed by the UK Department of Environment, Food & Rural Affairs.² A questionnaire was sent to local authorities (LA) to obtain information about the range and composition of industrial noise sources.

In Fig. 1 the range of industries identified by the LA is given, which covers the range of industrial activities. The size of the slices expresses the frequency of occurrence in the response of the LA. The category “Others” includes airfields/airports, brickworks, bus depots, civic amenity centers, drycleaners, dyeworks, glassworks, motor speedways, gas stations, and train depots.

Furthermore, the questionnaire requested information regarding the characteristics of the noise. The result is shown in Table 1. The survey shows clearly that tonality and impulsiveness are a very important part of industrial and commercial noise in the communities. Tonality and impulsiveness can usually be reduced by available mitigation technologies. The result of the above survey means that the best available technologies (BAT) for noise reduction are frequently not applied. However, even if BAT is applied and tonality and impulsiveness are avoided, a necessity remains to separate residential areas from areas with commercial or industrial activities to ensure that acceptable reception noise levels are not transgressed.

3 PLANNING

Communities are competing to obtain more and new enterprises to increase the number of jobs and tax revenues. Therefore, they design areas where potential investors may settle. To organize this such that the loudest plant is not directly positioned next to a residential neighborhood, a zoning of such areas is undertaken including the limitation of sound emission to the neighborhood. This limitation can be achieved by using the area related sound power level, L''_w .

The area-related sound power level is defined by

$$L''_w = 10 \log \left(\frac{I}{F} \frac{F_0}{I_0} \right) \text{ dB/m}^2$$

where I is the total sound power of the area under consideration of size, F , $F_0 = 1 \text{ m}^2$, and $I_0 = 10^{-12} \text{ W}$. This concept is described in Ref. 3.

When using area-related sound power levels, L''_w , it should be noted that under this concept it is

* "Other" includes Airfields/Airports, Brickworks, Bus Depots, Civic Amenity Centers, Dry Cleaners Dyeworks, Glassworks Motor Speedways, Petrol Stations, and Train Depots.

Figure 1 Frequency and significance of industrial sources as given by local authorities in Great Britain.

Characteristics	Percentage
Tonal	51
Impulsive	38
Low frequency	37
None	22

formally assumed that no barrier effect or similar additional sound pressure level reducing factors are taken into account as long as the propagation path of the sound from each unit area to the neighborhood travels within the source area under consideration. Therefore, propagation calculation can be done simply by taking into account spatial spreading, air absorption, and ground effects as described, for example, in International Organization for Standardization (ISO) 9613-1 and ISO 9613-2 up to the nearest residential neighborhood.⁴

Commercially available propagation software allows to plant area-related sound sources into a specific topographical situation at a specific height above the ground. Using this, the long-term L_{eq} or the downwind L_{eq} of such sources can be calculated. Figure 2 shows such a case in a flat terrain with housing in the neighborhood (rectangles). The white line between the residential and the commercial area depicts the periphery of the zone over which the sound power has been

equally spread. It is assumed that the area within the two white lines is not used.

The total area is 12,000 m²; this means that a total A-weighted sound power level of approximately 101 dB can be installed. It is obvious that using a nonuniform distribution of the sound power level in a 1-ha area could lead to the installation of higher sound power levels. A point source on the opposite side of the residential neighborhood would lead to the highest value and a point source close to the boarder line of the neighborhood to the lowest value. This consideration shows that for one investor this type of planning is unnecessary, however, if more than one investor is considered, the above scheme is useful to avoid conflicts between the investors and the neighbors. In this context it should be noted that screening produced by buildings allows to increase the sound emission of those areas, which benefit from this.

In land use nonacoustical considerations are important in relation to the neighborhood and possible use. Therefore, a subdivision of an area under consideration is usually a must. In this case, different zones for different values of L''_w can be introduced. Such a case is shown in Fig. 3 for seven different areas.

In Table 2 the area-related sound power levels are listed. In Fig. 4 the nighttime situation is depicted in a nonflat topographic situation, including berms for noise protection. As this figure shows, the neighbors to the west will receive A-weighted noise levels up to 48 dB and those to the east 44 dB for the most exposed sites. Most of the neighbors to the west have A-weighted noise levels

Figure 2 Reception A-weighted noise level distribution around an area-related source with A-weighted $L''_W = 60$ dB/m², 0.5 m above ground having a length of 120 m and a width of 100 m. The calculation is done for a receiver height of 1.5 m above ground. The diagram was calculated using LIMA, a product sold by Bruel & Kjaer.

Figure 3 Planning with different area-related sound power levels.

Table 2 List of Area-Related A-weighted Sound Power Levels

	L''_W Night	L''_W Day	
Area I, production	54	59	dB/m ²
Area II, maintenance	47	59	dB/m ²
Area III, storage area	45	59	dB/m ²
Area IV, storage area	45	59	dB/m ²
Area V, parking	44	50	dB/m ²
Area VI, production	54	59	dB/m ²
Area VII, ^a berms	30	30	dB/m ²

^aJust for berms for noise protection etc.

below 43 dB and to the east below 40 dB, which are the limiting values allotted to those areas for the nighttime.

On the other hand, the area-related A-weighted sound power levels given in Table 2 show that only areas II and IV have nighttime values of 54 dB/m²; the rest of the area is well below those values. This separation means that the louder part of a production should be concentrated in these areas. Area VII is around the noise protection berms and the values of 30 dB/m² mean that absolutely no machinery should be installed there. The allocation and size of the areas have been chosen according to the landscape, transport roads, and the like. The purpose of this planning was to ensure that conflicts that occur at present can be reduced in the long term to an acceptable level for the neighborhood, which is mainly residential to the south east and mixed in the north and south.

4 TYPICAL AREA-RELATED SOUND POWER LEVELS

The amount of sound power emitted from a typical plant such as a steel mill or a refinery depends strongly on the state of noise protection measures undertaken. It is, therefore, not possible to say a chemical plant of such a type has typically a specific sound power level. For practical purposes, it has turned out that it is sufficient to subdivide industrial and commercial noise sources into the following categories:

1. Open-air plants (e.g., petrochemical production, refineries, chemical plants, scrap yards, quarries)
2. Plants operating in buildings where parts of the process are outside (pharmaceutical production)
3. Plants in buildings, only auxiliary units such as cooling towers on the outside
4. Complete indoor production, only transport noise on the outside (e.g., car industry)

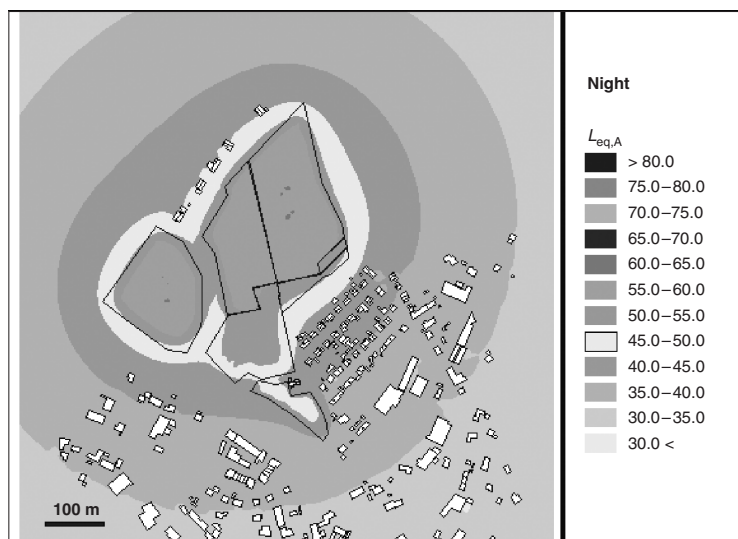

Figure 4 Night situation in a nonflat topographic area including berms for noise protection 6 m above ground. North direction is to the top. The equivalent sound pressure levels given are A-weighted.

5. Logistic centers (transport and truck noise)
6. Machine working outdoor
7. Manufacturer
8. Shopping malls
9. Shops, repair shops, and trade companies
10. Small shops such as bakery, butcher, open-air restaurants (beer gardens)

Categories 1 to 5 deal with industrial and categories 6 to 10 deal with commercial noise.

In most countries, noise resulting from hotels, restaurants, and the like is considered to fall under commercial noise; however, the specific noise problems from these enterprises are usually dealt with on the basis of specific legal regulations.

In Table 3 area-related A-weighted sound power levels are given and the type of plants in which they occur. Commercial or industrial production with levels below 45 dB/m² is almost impossible. This can be

seen from a simple consideration. Assuming that 10 cars drive at night to and from the parking per hour lot of the premise under consideration. One parking per hour produces an area-related A-weighted sound power level of $L''_W = 65$ dB/m²⁵. Each parking lot has an area of 10 m² per car, which leads for 20 movements to an A-weighted sound power level of 88 dB per hour. The cars themselves have to be driven to the parking lot over a distance of 200 m at a speed of 30 km/h. Twenty movements per night lead to an A-weighted sound power level of 83 dB. In total, one obtains 89 dB or an average A-weighted sound power level of 80 dB per night. If this sound power level is spread over 3,000 m², the 45 dB/m² are reached.

Typically, a fork lift has an A-weighted sound power level of 95 dB to 102 dB during operation. One fork lift continuously operating in an area of 100,000 m² or 10 ha will produce 45 to 52 dB/m² area-related A-weighted sound power levels. On the other hand, a front loader in a scrap yard typically

Table 3 Type of Plants and Area-Related A-weighted Sound Power Levels

Area-Related A-weighted Sound Power Level (dB)	Plants
70–75	Open-air plants such as shipyards, refineries, open-air plants with few noise protection measures
65–70	Open-air plants such as refineries, integrated steel mills, chemical productions using state-of-the-art noise protection
60–65	Container terminal, louder equipment, steel mills, indoor, waste processing
55–60	Production mainly in buildings
50–55	All production in building, some transport noise, cooling towers
45–50	Indoor production without noticeable outdoor activities
35–45	No production. Warehouses with cooling etc. are possible

produces A-weighted sound power levels of 115 dB. A typical scrap yard has an area of 5 ha. If the front loader is operated for 4 h a day, the area related A-weighted sound power level is

$$\begin{aligned} L''_w &= 115 - 10 \log F/F_0 - 10 \log 4/16 \\ &= 62 \text{ dB/m}^2 \end{aligned}$$

A typical steel mill using BAT for noise reduction has an A-weighted sound power level of 123 dB during nighttime for a production of one million tonnes of steel per year, using an electric arc furnace and a rolling mill to produce specific products. If the area under consideration allows 60 dB/m², an area of 100 ha is needed, if 65 dB/m² would be possible, only 33 ha would be needed.

These examples show that the concept of area-related sound power levels allows land-use planning on one side and gives possible investors a perspective whether or not a specific area is suitable for the production under consideration. Furthermore, it allows an estimation of whether or not investments in noise protection will be necessary to avoid complaints from the neighborhood, legal actions, and so forth.

5 MEASUREMENT OF COMMERCIAL AND INDUSTRIAL NOISE

5.1 General Considerations

There are two basic approaches for the measurement of industrial and commercial noise, depending on the size of the industrial or commercial activities under consideration. If the noise level for a small enterprise with few sources has to be established and the resulting rating level, L_r , to be compared with a legal limit, the measurements should be done for those sites in the neighborhoods that are of primary interest. If, however, a large number of complaints are observed and the enterprises consist of a larger number of sources, it is more suitable to measure the sound power level of all sources that might sufficiently contribute to noise in the neighborhood. This should cover all sources, which together contribute at least 90% of the A-weighted sound intensity received by the neighborhood. Additionally, all sources have to be measured, which are tonal or impulsive or of low frequency (less than 90 Hz) with respect to the definition of the rating level, L_r . For example, in Germany the daytime rating levels are calculated as the energy average over 16 h of the day, where the hours between 6 and 7 a.m. and those between 7 and 10 p.m. are rated with an addition of 6 dB. During nighttime the rating level of the noisiest hour is compared with the limiting value for the nighttime. This means that the hours during which certain sources appear have to be taken into account.

The sound power should be measured at least in octave bands. However, high-resolution sound power spectra are of great help to identify tonal sources and can easily be obtained using the Fast Fourier transform (FFT) algorithm. With commercially available software, which uses generally either A-weighted levels or

octave bands, the industrial source can realistically be modeled and noise maps can be calculated, from which the reception noise level and its rating level, L_r , at a specific height can be obtained, which allows to assess the noise at all possible sites in the neighborhood.

The additions necessary to express the impulsiveness and tonality can be included by adding them to the sound power of the source. It might be necessary to add higher values to obtain the proper rating levels. The advantage of this approach is that noise reduction measures can be quantified very precisely to reduce the rating levels below the legal limits.

5.2 Measurements at the Reception Site

In almost all cases where complaints are received with respect to industrial noise, the distance to the industrial source is less than 1000 m. Measurements should be performed under favorable sound propagation conditions (see, e.g., ISO 1996-2).⁶ This can be expected for all situations where due to temperature and wind gradient the curvature of the sound wave is downward. During daytime and especially for situations with open sky, this situation may be assumed if the wind blows from the source to the receptor site at an angle up to 60°. At nighttime, especially for situations with open sky favorable conditions can be assumed if the wind speed is less than 0.5 m/s or at higher speeds and wind direction between ±120°. If the sky is clouded, downwind can be assumed for up to 90° (see, e.g., ISO 1996-2).⁶

Using three-dimensional wind meters, which measure the speed of sound in vertical and two horizontal directions, the temperature and wind gradient vector in the atmosphere can be estimated using methods from boundary layer meteorology⁷ as a function of height for heights above ground of more than 100 m, which is sufficient for sound propagation. The respective software is provided with these instruments.

If the distance is less than 100 m, meteorological influences on sound propagation are small; for distances of more than 100 m measurements they should be performed under favorable sound propagation conditions. According to a large number of continuous acoustical monitoring measurements, the variance 6σ of stationary industrial sources reaches at 1000-m values between 3 and 4 dB starting at 100 m with 1.5 to 2 dB and a measurement time of at least one hour. This variance means that repetitive measurements are necessary to ensure that sufficient precise results for favorable sound propagation situations are obtained.

If it is assumed that the limits of confidence for energy-averaged mean value $\overline{L_{eq}}$ are similar as for the mean value of all levels that could be measured under favorable sound propagation conditions, the upper and lower limit of confidence $L_{eq\pm}$ for $\overline{L_{eq}}$ can then be approximated by

$$L_{eq\pm} = \overline{L_{eq}} \pm \frac{\sigma(r)}{\sqrt{n}} Z_\alpha$$

where Z_α denotes the percentile α of the normal distribution, n the number of independent measurements, and σ the variance as a function at distance r

under downwind conditions; $Z_\alpha = 1.96$ describes the coverage probability of 95%, which means that the true value of the L_{eq} falls with a probability of 95% within the above limits. The above relationship shows that for one measurement ($n = 1$) at a distance of 1000 m the limits of confidence are between ± 6 and ± 8 dB and at a distance of 100 m between ± 3 and ± 4 dB. This means that repetitive measurements are usually necessary if measurements are taken at distances of 100 m and more.

It should be noted that the observed variance is produced by the variation of the propagation conditions, which tend to change from day to day and not from one hour to the next. This means that the time between two measurements has to be at least one day to ensure that the measurement results are independent.

To reach a limit of confidence between ± 3 and ± 4 dB for a measurement at 1000 m distance at least five independent measurements are necessary (see, e.g., DIN 45645-1).⁸ It should be noted that the total measurement uncertainty has to include possible deviations produced by the measurement equipment (see Ref. 9).

Other statistical approaches may be used such as the assumption that the square of the sound pressure is lognormal distributed or equally distributed. These assumptions may lead to slightly different limits of confidence.

If the rating level, L_r , is defined as long-term L_{eq} , a correction for the frequency of occurrence of unfavorable sound propagation conditions may be used according to ISO 9613-2.⁴ In this case the factor c_0 in Eq. (8) of ISO 9613-2 may be chosen to be 2 dB at night-time and 5 dB during daytime and 3 dB for the evening and morning ± 2 h around sunrise and sunset. These corrections may produce additional deviations, which can be incorporated by an error calculus as described in ISO 3723 or GUM.⁹

In practical application, the rating level has to be compared with a limiting value X . In those cases where the measurements are done to prove that the situation is in compliance with the limiting value X , one has to proof that

$$X > \bar{L}_r + \frac{\sigma(r)Z_\alpha}{\sqrt{n}}$$

or if one has to prove that the noise levels are above the limiting value X

$$X < \bar{L}_r - \frac{\sigma(r)Z_\alpha}{\sqrt{n}}$$

However, this leaves open the question what has to be done, if the limit X is within the range given by the limits of confidence $L_{eq\pm}$. If this range is smaller than 3 dB, one can assume that the situation under consideration does not deviate significantly from the legal limit.

5.3 Sound Power Levels

If model calculations are used to establish the rating level, the sound power of the relevant sources has to

be measured. The possible measurement errors result from the number of independent sources to be measured and modeled. If the standard deviation of the proposed measuring methods (see, e.g., ISO 8297, ISO 3744, and ISO 3746)¹⁰⁻¹² is ± 3 dB, the limit of confidence ($Z_\alpha = 1.96$) reduces for 10 sources to ± 2 dB, if 100 sources are involved to approximately ± 0.2 dB if all sources have a comparable contribution at the reception site. If this is not the case, an error calculation has to be used that allows to weight the uncertainties with respect to the sound power of the sources.

The most frequently used standard for sound propagation calculation is ISO 9613-1 and -2.⁴ Part 1 deals with air absorption and Part 2 with the other factors governing sound propagation. According to Table 8 in Part 2, the possible errors for a downwind calculation at a distance of 1000 m is 3 dB. This means together with the measurements errors of the sound power measurements a total error Δ :

$$\Delta = \sqrt{3^2 + 3^2} = 4.24 \text{ dB}$$

for each source. For 10 sources one obtains the limit of confidence as follows:

$$L_{eq\pm} = L_{eq} \pm 1.34 \text{ dB}$$

a range comparable to those of measurements in the neighborhood. The only assumption is that the errors of the sound propagation model of ISO 9613-2 can be considered to be random and not systematic in nature.⁴

According to a large number of projects done to measure the sound power levels of up to 500 sources to evaluate the reception noise in the neighborhood of large industrial complexes, such as refineries, steel mills, and harbors, it could be shown that the deviation between long-term measurements up to 1 year and calculated levels falls well into a range of ± 1 dB. Judging from this, it can be assumed that for more than 10 sources the errors of the ISO 9613-2 sound propagation model behave randomly.⁴ For smaller numbers this is not the case and control measurements at distances of about 100 m are recommended.

6 AVOIDING COMMUNITY REACTIONS

As can be seen from Fig. 1 and Table 1 in more than 70% of the cases, tonality, impulsiveness, and low-frequency noise seem to be the dominant cause of community reactions. The approach to reduce community reaction is simple—avoid these types of noise and avoid reducing the stationary sources to a level where the unavoidable intermittent sources can be heard in the neighborhood. If the legal limits are transgressed, noise reduction should concentrate on the intermittently audible sources. The reduction of the stationary part should be such that the intermittently occurring sources do not get more prominent. This is in line with numerous cases this author has been involved.

If there are complaints and the sources are known, few measurements and model calculations are sufficient to establish the situation and to find a technical

solution. However, in most cases the situation is more complicated. The company under consideration claims that the sometimes observed tonal, impulsive, or only very loud events are caused by something or someone else or are just the invention of neighbors. In these cases long-term measurements including the continuous recording of the sound is a sufficient method to establish whether or not such noises occur. According to this author's experience, in most cases complaints are well founded. The classical exceptions are tinnitus and psychological problems. The advantage of continuous monitoring is that the often heard complaints by neighbors can be excluded, that the auditor only appears when it is quiet, and that the company knows that he was coming. Especially if short-term very loud unknown activities are involved, continuous monitoring has proven to be a very efficient method to find the cause of complaints. The installation of long-term recording equipment leads to reductions of the emotional stress felt by both the company under investigation and the neighbors. Furthermore, the results are usually accepted by both sides, due to the fact that events, time, and impulses are well documented.

In cases where the limits are transgressed and a short-term technical solution is not possible, the acceptance by the neighbors can considerably be increased if the neighbors are invited to see the production during a day of open doors, which includes communication with the management on a casual basis. It also helps if the public and local community are regularly informed about measures taken and level reduction achieved, even if those reductions are well below 1 dB.

Of further help is if the neighbors obtain a telephone number to which they can talk at all times of the day. However, it is a must that the personal at the receiving side be trained to take those calls.

CHAPTER 129

BUILDING SITE NOISE

Uwe Trautmann
ABIT Ingenieure Dr. Trautmann
Teltow/Berlin, Germany

1 INTRODUCTION

Residents living near to inner-city building sites are frequently affected by the noise emitted by building sites, which disturbs sleep, mental concentration, and speech communication. The neighbors' right to rest is in conflict with the contractors' interest in performing building work in the shortest possible time and with intense utilization of the equipment and machinery. Local authorities may also take an interest in short construction times in order to limit disruptions to road and rail traffic and public utilities.

Although an inner-city building site may cause significant annoyance to the immediate neighbors, there are relatively few standards for the prediction of ambient noise, for example, from power plants. Some exceptions include test codes available for building site noise in Germany and the United Kingdom. These test codes provide tools for the calculation of the daytime and nighttime rating levels, which are compared to standard ambient-noise values. In addition, transient noise peaks can be considered.

2 GENERAL APPROACH, SOUND SOURCES

This chapter is mainly based on the practice in Germany and the United Kingdom. Conflicts must especially be avoided in the case of large-scale, long-term building projects. This calls for the following actions:

1. Preparation of a prediction of the expected ambient-noise values during the various building phases.
2. Assessment of ambient-noise values. Elaboration of a noise control program. Consideration of technical and organizational noise control measures.
3. Reconciliation/harmonization of the interests of builder-owner/contractor and neighbors in terms of an (administrative) special permit or a civil-law agreement. These documents may specify building technologies, machine utilizations, work hours, or maximum ambient-noise values.

The following are typical causes for inner-city building sites:

- Demolition of buildings including underground parts
- New constructions (foundation work, main works, facade, completion work, open areas)

- Road and rail construction
- Sewerage construction (open method, underground forcing)

Table 1 provides an overview of the most frequently used construction machines and their sound power levels during normal operation.

The characteristic noise emission value is the A-weighted sound power level averaged over the duration of several work cycles (L_{WAeq}). For an assessment, the maximum level may also be required (L_{WAmax} , $L_{WA1\%}$); this level is usually determined by the process noise (effect of the construction material).

As per EU Directive 2000/14/EC, within the European Union many of the construction machines put on the market are subject to noise marking.⁶ This means that the manufacturer must state the guaranteed sound power level in the operating instructions and on the machine. Operating conditions are given; alternatively, a machine-specific standard is cited (usually stipulating a simulation of a typical work cycle without construction material). Determination of the sound power is usually in accordance with ISO 3744.⁷ Furthermore, some of these machines are subject to sound power limits (see Table 2).

The sound power radiated by a construction machine during actual operation on site is often less than that stated by the manufacturer.⁸ On the one hand, this is a consequence of the standardized measurement conditions that stipulate maximum engine speed during the entire measurement; on the other hand, a penalty is added to the measured value declared so as to take into account the variance in noise emission between the individual machines (ISO 4871).⁹ In some building technologies, the process noise may also be dominant (e.g., when sorting scrap metal). A database provides an extensive compilation of noise emission values for construction machines (standard and in-situ data).¹

3 AMBIENT-NOISE PREDICTION

Figure 1 illustrates the general procedure of site noise prediction. To begin with, ambient-noise values due to individual building works, phases, or zones are calculated. Where the time schedule shows that building works are performed simultaneously, their contributions to the sound pressure level at the points of reception are summed up on an energy basis. The sound power levels of the machines in use can be found in Table 1 or measured values obtained in situ are used as a basis. Penalties for impulsiveness and

Source: From Ref. 6.

tonal character are added as specified in the relevant national regulations stipulating the determination of the rating level. Depending on the characteristic acoustical quantity, the penalty for impulsiveness may already be included in insitu values:

$$L_{WA,r} = L_{WA,eq} + \Delta I + \Delta T \quad (1)$$

where $L_{WA,r}$ = rated sound power level for continuous operation of a construction machine

$L_{WA,eq}$ = equivalent continuous sound power level of a construction machine, e.g., during standard operation as specified⁶

$\Delta I, \Delta T$ = penalties for impulsiveness and tonal character, usually 0 dB to 6 dB

As a rule, none of the construction machines sustains uninterrupted acoustically significant operation throughout the time to be rated. Intermittent operation of the machines reduces their sound power as taken into account in the calculation of the rating level (time-average level):^{2,10,11}

$$L_{WA,r,t} = L_{WA,r} + 10 \log(t/T) \quad \text{dB} \quad (2)$$

$$L_{WA,r,t} = L_{WA,r} + 10 \log(p/100) \quad \text{dB} \quad (3)$$

where $L_{WA,r,t}$ = rated sound power level referred to actual time of use of a construction machine

t = acoustically effective time of use of a construction machine during the time to be rated

T = time to be rated (e.g., daytime 13 h, nighttime 11 h)

p = percentage utilization rate of a construction machine, $p = (t/T)$ 100% (see also Table 1)

The specification of the position of use of a construction machine is not critical if the extent of the potential range of use during the time under consideration is

smaller than twice the distance to the nearest point of reception. As a rule, it will suffice to simulate the construction machine in terms of a stationary point source. The working range of a construction machine, or of a construction process, can also be represented as a two-dimensional or linear sound source:

$$L''_{WA,r,t} = L_{WA,r,t} - 10 \log(S) \quad \text{dB} \quad (4)$$

$$L'_{WA,r,t} = L_{WA,r,t} - 10 \log(l) \quad \text{dB} \quad (5)$$

where $L''_{WA,r,t}$ = sound power level per unit area of a construction machine having $L_{WA,r,t}$ (see above)

$L'_{WA,r,t}$ = sound power level per unit length of a construction machine having $L_{WA,r,t}$ (see above)

S = area of working range, in m^2 (e.g., part of building zone)

l = length of path traveled, in m (e.g., site road)

Energy-based summation allows to combine several construction machines to give one two-dimensional sound source, for example, for reinforced-concrete works: circular saw, hammer, crane, truck mixer, concrete pump, and internal vibrator.¹¹

Commercially available computer software calculating sound propagation from the site to the points of reception on the basis of ISO 9613-2 determines the contributions of the construction machines/processes to the rating level, using $L_{WA,r,t}$ and the pertinent distance (d) to the point of reception in question.¹² With geometrical sound radiation (omnidirectional radiation over a sound reflecting plane), for distances $d \lesssim 100$ m the sound pressure level is

$$L_{r,i} = L_{WA,r,t,i} - 20 \log(d) - 8 \quad \text{dB} \quad (6)$$

$$L_r = 10 \log \sum_i^n 10^{L_{r,i}/10} \quad \text{dB} \quad (7)$$

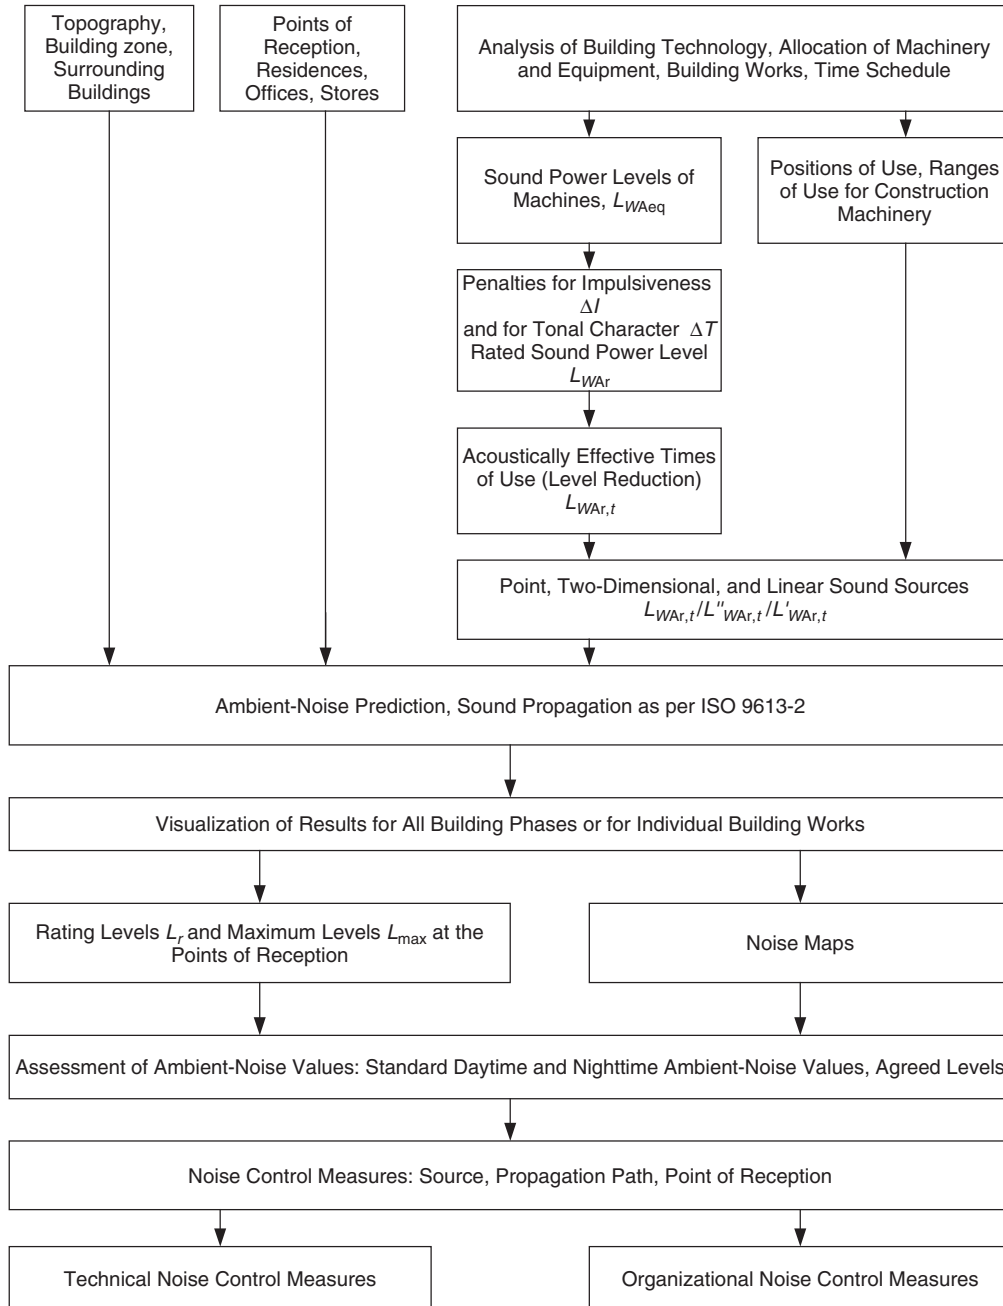

Figure 1 Procedure of site noise prediction.

$L_{WA,r,t,i}$ = rated sound power level of construction machine no. i
 $L_{r,i}$ = contribution of rated sound pressure level of machine no. i at point of reception
 L_r = total rated sound pressure level at point of reception

d = distance between construction machine and point of reception, in m
 n = number of construction machines

In addition, sound reflection (including absorption) and screening are taken into account. For the purpose

of sound propagation calculation, two-dimensional and linear sound sources are split up into point sources depending on their distance to the point of reception. The calculation of the maximum sound pressure levels at the point of reception is performed in an analogous way, albeit without time correction, assuming the maximum sound power L_{WAmax} or L_{WA1} %.

As a rule, ambient noise from building sites is calculated for the facade of the rooms requiring protection. In individual cases (especially in case of very high sound pressure levels), the indoor sound pressure level may be calculated and compared to standard levels (e.g., for living rooms and bedrooms, offices, and conference rooms). This is done on the basis of the sound insulation of the facade with windows closed. In order to ensure the minimum air exchange rates required by various room usages, ventilation intervals that increase the indoor rating level must be taken into account in buildings without ventilation system.

Usually the uncertainty of ambient-noise predictions for building sites lies in the range of ± 3 dB; no results are available of systematic investigations on the uncertainty. The predicted sound pressure level is mainly a function of the accuracy of the sound power (L_{WAeq} , L_{WAr}) and the assumed time of use (t , p) of the most noisy construction machines.

4 MEASUREMENT OF SITE NOISE

As is the common procedure with ambient-noise control, measurements are usually carried out immediately at the points of reception or at substitute locations whose results are converted for the points of reception.¹⁰ Extraneous noise not part of the site noise must be recorded separately for correction of the measured values or excluded during the measurements (e.g., traffic noise).¹³

The measurands (sound pressure levels) are stipulated by the laws and standards that are to be used for the assessment (e.g., L_{AFeq} , L_{Aeq} , L_{AFTm5} , L_{AFmax} , $L_{AF1\%}$, and $L_{AF10\%}$). Penalties for the calculation of a rating level (L_r) are sometimes estimated (e.g., $\Delta L_f = 0$ to 6 dB).¹⁰

In the case of short-time measurements, the noise is recorded and averaged over a representative period. The rating level may then be calculated for the time to be rated by taking into account a level time correction (see Section 3). Extraneous noise can be identified and taken into account immediately.

In the case of continuous measurements, the levels of interest are recorded continuously over time. The rating levels for the times to be rated (e.g., daytime/nighttime) are calculated on this basis. Extraneous noise can only be identified by recording the time signal and subsequent "listening" to the recording (e.g., church bells, air traffic noise, or user noise at the point of reception).

Continuous sound pressure level measurements also allow good control of the compliance with work restrictions imposed on the building site (beginning and end of work hours, compliance with agreed rest

periods, restrictions to the use of machinery). Measurements on individual construction machines allow the determination of their sound power during use to be used as the basis for the predictive calculation (L_{WAeq} , L_{WAr} , $L_{WAr,t}$).⁷

5 ASSESSMENT OF SITE NOISE

The predicted or measured sound pressure levels at the points of reception are compared to the standard values stipulated in laws or standards or to sound pressure levels agreed upon in the noise control program. Limits for site noise do not exist on the international level, but they are available in Germany and some other countries. Standard ambient-noise values for site noise depend on the specific ambient-noise regulations in individual countries (e.g., rating levels for daytime and nighttime, additional limits for noise peaks during the night).

The disturbance caused by a building site lasting for a limited time only, ambient-noise values exceeding the standard ambient-noise values for stationary plants by 5 dB to 10 dB are admitted in some countries, depending on the duration of the building works (higher levels for shorter times).

The following arguments are usually taken into consideration in the assessment of site noise:

- In some cases, the use of construction machines may be limited depending on the type of machine and the legal ambient-noise classification of the area in question. Ambient-noise predictions may present reasons for exemptions.
- The approving authorities must enforce the neighbors' right to rest while also considering the builder-owners'/contractors' interests as well as public interest.
- Number of persons concerned.
- Intensity of exposure (difference between actual level and standard level, duration of noisy building works).
- Acoustical masking by other sound sources, for example, traffic noise.
- Reduction of overall duration of work, for example, where public traffic or commercial activities are impaired (nighttime building site required).
- Strong impairment of the quality of life and housing (night's sleep disturbed depending on the work and life rhythm, further annoyance caused by dust, exhaust gases, and vibrations).
- Neighbors' right to rest (especially night's sleep) to be pondered against technical necessity of the building methods.
- Right to working conditions as given in occupational health and safety regulations during daytime (offices, stores).
- Building contractor's or builder-owner's interest in an undisturbed progress of the building works (no interruptions due to complaints, lawsuits).

- Reduction of cost by two- or three-shift operation.

Special permits for site noise during the daytime may be granted, if

- The standard ambient-noise values are expected to be exceeded considerably.
- The contractor wishes to secure a legal basis for his interest in an undisturbed progress of the building works.

A special permit is required for the nighttime, if

- Modern building technologies call for continuous operation, making work during rest times unavoidable (as is the case, e.g., with high-pressure injections, large-scale concrete works).
- operation in at least two shifts (6 a.m. to 10 p.m.) is desirable for reasons of time and cost.
- work can only be performed during the nighttime because of the closing of roads or railways.

- Nighttime work causes less disturbance because the area is exclusively used for offices and stores.

6 NOISE CONTROL MEASURES

Establishing a noise control program is decisive for the effective functioning of noise control measures (acoustical and economic).³ Noise control measures shall

- Start at the noisiest sources.
- Come into effect especially during rest periods.
- Be made known and explained to all those concerned (building contractor, authority, neighbors).

The noise control program should comprise the following steps:

1. Analysis of the building site. Where and when are noisy machines/processes used?
2. Ambient-noise prediction for the neighbors concerned (see Section 3).

Table 3 Technical and Organizational Noise Control Measures for Building Sites

No.	Measure	Note
1	Noise control at source	
1.1	Change building technology, use low-noise building methods; e.g., laying of prefab concrete parts, concrete works in limited areas using buckets instead of pump. Sawing, milling, or use of hydraulic tongs instead of demolition by pneumatic or hydraulic chipper. Pressing or vibrating, rather than pile-driving, of pit boards.	
1.2	Use low-noise construction machinery.	Strive for an acoustical balance. Noise control measures on construction machinery must, as a rule, be agreed with the manufacturer. Consider safety regulations where the reversing alarm is disabled.
1.3	Covering of toughs and filling holes with rubber. Damping of metal sheets.	
1.4	Restrictions (spatial, temporal) to the use of individual construction machines or processes.	Illustration of the ranges of use in the site plan, allocation of times of use.
1.5	Temporal and spatial organization of the site following the motto: Assign noisy building methods to noisy building phases/times, and low-noise building methods to low-noise building phases/times.	For example, plan on maximum use of machinery during daytime in order to ensure night's rest for neighbors.
1.6	Coordination of building times: Plan beginning and end in accordance with the legal ambient-noise classification (e.g., residential area, offices only, health resort area). Shifting or even exchanging daytime and nighttime works. Consideration of neighbors' typical rest times.	For example, in office-only areas: Noisy nighttime work is convenient (but consider sound propagation to remoter residential areas). Health resort areas often favor short overall building times (nighttime work, e.g., out of season).
1.7	Reduction of daily work time.	Unfavorable from building technology viewpoint, often causing excessive prolongation of overall building time.
1.8	Adaptation of running of construction machines with actual used power. Avoid idling especially during rest hours.	
1.9	Maintenance of construction machines.	Avoid vibration/rattling of cover sheets.
1.10	Instruction of employees on low-noise work. Avoid shouting. Use of radiotelephony for communication.	Use especially during rest hours. Use of tower crane loudspeakers only in case of emergency.

Table 3 (continued)

No.	Measure	Note
1.11	Supervision of building site (machines used, technology, work hours, work ranges).	Safety service.
2	Measures taken on the sound propagation path	
2.1	Increase distance between noisy building processes and points of reception. Allocate building zones in large-scale projects. Organize site traffic (delivery and disposal of construction material). Machine locations.	Give particular consideration to rest times, shift nighttime building activities to remote building zones.
2.2	Screening of construction machines/processes (installation of separate screens).	For example, formwork material, scaffold curtains, flexible materials, containers. Screens are only effective if placed close to the source. Consider all points of reception; those opposite the screen may be subject to an increase in sound pressure level! See also 2.2.
2.3	Use already erected building parts as acoustical screens.	
2.4	Enclosing or partial enclosing of machines and processes.	Sound insulation of the enclosure material, sound-absorbent cladding, proper sealing. Silencers on unavoidable openings (cooling air, exhaust gases). Orientation of partial enclosures, see also 2.2.
2.5	Avoid positioning of construction machines in front of sound reflecting surfaces.	
3	Measures at point of reception	
3.1	Inform neighbors, possibly in the form of a hearing prior to starting the building project, regular information about progress.	Unaddressed mailings, informative dioramas.
3.2	Improve sound insulation of windows.	Only effective as long as windows stay closed. Allow for ventilation: Ventilation system, sound-insulated ventilation elements. In the case of natural ventilation via the windows, consider ventilation intervals when calculating the rating level.
3.3	Provide substitute accommodation. For example, offer hotel accommodation for short-time building projects.	In case of short-time building projects, experience shows that neighbors tend to solve problems on their own by sleeping with windows closed. Accommodation may also be offered by relatives or acquaintances.
3.4	Agree on financial compensation (owner, landlord).	
3.5	Invite neighbors to social events (such as laying of foundation stone, ceremonies on completion of building pit/ceilings, topping out/dedication ceremonies).	
3.6	Inform the competent authority. Obtain special permit, agreement on special requirements. Inform the police precinct concerned.	The special permit can cover measures from rows 1 through 3.
3.7	Sample measurements or continuous monitoring of ambient-noise values. Regular information of neighbors, the authority, and the contractor about measurement results.	Continuous measurements allow to verify noise control measures (such as compliance with work hours, restrictions to use of machinery).
3.	Assessment of site noise (see Section 5).	
4.	Elaboration of technical and organizational noise control measures for all building phases, taking into account the acoustical effect and the cost.	
5.	Regular information of the neighbors about the work progress. Special information prior to noisy events (such as large-scale concrete work during nighttime).	
6.	Updating of the noise control program (repeat steps 1 through 5).	
Depending on the sound propagation conditions, noise control measures can be implemented at source, on the propagation path, and at the point of reception. Measures taken at source have the greatest acoustical effect in inner-city building sites, as many neighbors are affected by site noise at the same time. The most		

important measures for noise control are compiled in Table 3.

CHAPTER 130

COMMUNITY NOISE ORDINANCES

J. Luis Bento Coelho

CAPS—Instituto Superior Técnico
Lisbon, Portugal

1 INTRODUCTION

Sound produced by human activities, transportation, machinery, and by nature itself is always present in a community. Such sounds, when unwanted, are perceived as noise. Each person perceives noise by taking into account a vast number of different factors including personal, cultural, economic, and societal. This makes the perception of noise very subjective.

Noise may be understood as an expression of human activity, but it can also be a source of annoyance. People make noise; however, noise is not a problem unless it becomes excessive, thereby hindering the community quality of life. This calls for each community and its government to set up policies for noise management and control and to devise and enforce strategies for noise abatement.

Community noise ordinances have been passed in most countries to address noise issues of all types, from neighborhood to transportation. They deal with noise limits at the receiver as well as with the quality of noise itself. Such ordinances can be qualitative or quantitative; they can be emission or receiver based. As part of the actions of a global noise policy, which includes sustainable development, community noise ordinances can be instrumental tools that ensure a noise-controlled environment.

2 COMMUNITY NOISE AS A PROBLEM

Community noise can be described as unwanted sound in a nonoccupational setting. Major sources of community noise are transportation systems, industry, construction, leisure activities, and neighborhood with transportation being the main contributor. Industry can contribute to the overall noise, especially in some suburban or rural areas. Leisure activities may account for a significant part of the noise in some areas of the community. Noise from equipment, either outdoors (construction, air conditioning, ventilation systems) or indoors (lifts, home appliances) is also a part of the overall noise.

Noise in a community must be addressed in terms of quantity and of quality. Once the quantity of noise is reduced, the quality becomes important. People usually have an expectation for the way different noise sources in the environment should sound. In quieter communities or in those where noise has already been reduced, this expected sound quality assumes a higher importance.

The larger and more complex a community is, the higher is the number of noise sources and the more difficult it is to act for noise abatement purposes. In a city, the complexity and intricacy of the human, economical, and social activities make urban noise management and control a difficult issue. Actions must

be devised and applied with the utmost care so as not to affect or disrupt the rhythm of life and the socioeconomic texture of the city.

Noise becomes a problem whenever the noise levels are high or when the number of complaints becomes relevant. The recognition of the noise problem must be followed by firm actions at the different levels of authority.

Noise was recognized as a problem in cities as early as the 1920s, although complaints from noise can be traced back to the Roman Empire due to the noise produced by the cart wheels on the pebble roads. With increasing population density, communities became noisier. In the last decades of the twentieth century, many cities in different parts of the world, namely in the United States, Europe, Japan, and Australia, for example, faced the problem of urban noise very seriously. Noise ordinances were promulgated and noise abatement became a prominent factor in urban planning and development.

3 NOISE ABATEMENT RESPONSIBILITIES

Success in the control of noise in a community can only be effectively achieved by a shared responsibility approach. Different levels of responsibilities can be established: local, regional, national, and federal. Community noise is a local problem. However, the solutions are not always necessarily local. Noise levels at a receiver are determined not only by local conditions but also by noise emissions whose limits or parameters are established above local or even national policies.^{1,2} Noise from industry, for example, depends on the equipment and machinery noise power but also largely on factory layout and on installed noise control procedures and devices. This is basically a local problem. Road traffic noise depends on the road profile and on the type of pavement but mostly on traffic density and on vehicle emissions. However, limits for noise emissions by road vehicles, as by rail or aircraft, are established at national or federal level.

Noise regulations must then consider all levels of action, sharing the necessary responsibilities for each type of noise source as appropriate. The regulations at different levels must be coordinated and consistent. Provisions must also be made for the allocation of corresponding technical and financial resources for an effective enforcement at all levels.

4 COMMUNITY NOISE REGULATIONS

Community noise regulations are a fundamental part of a noise protection policy as they raise the awareness of citizens to noise and to noise effects and reduce

the production of noise in many circumstances. They establish the basic criteria for the acoustical quality of the environment and set the objective noise values that define the noise abatement purposes. These regulations require actions from lower levels of government, from transport authorities, and from other bodies responsible for noise sources and noise emissions. They establish law compliance mechanisms and penalties, making it a platform for the common citizen to be aware of his duties and to demand his rights.

Noise ordinances may define the excessive noise by its character or nature. They may prohibit certain activities, restrict activities to certain hours of the day, require permits or licenses for noisy activities, or merely define noise zones. These are qualitative ordinances. These ordinances do not include quantitative criteria and may therefore pose some difficulties such as vagueness, as they are generally subjective in nature. Community noise ordinances usually took this form in the past. They can be recommended as a first approach to raise the issues of self-regulation and noise control or for those communities where the noise problems are either not too severe or are caused by locally well-controlled noise sources. Costs associated with the enforcement of qualitative regulations are usually relatively low since the corresponding technical requirements do not have to be too sophisticated.

Quantitative ordinances, on the other hand, establish numerical values as limits for the noise levels produced or received. Criteria are defined and standards are required for measurement or prediction of noise. Maximum permitted noise levels are generally expressed in A-weighted sound pressure levels and may vary for different areas of the community and for different types of noise sources as appropriate. This type of ordinance is recommended for communities where the noise problems are more complex or where a more stringent management of noise must be met. Good results, though, require that technical facilities (know-how, acoustical technicians and engineers, measuring apparatus) either exist or are created, and such costs must be envisaged when the ordinance is being drafted. Qualitative and quantitative ordinances are both valuable, although a composition of both features usually prove to lead to the most effective noise ordinance contents.

Noise ordinances can be of two types: emission laws or receiver-based laws. Emission laws and regulations regulate noise at the source, by establishing limits to the amount of noise emitted by equipment. Maximum permissible noise levels are defined for each type of machinery, vehicle, transportation, or activity. Receiver-based laws regulate the noise levels received at a particular site. Limits are defined for the noise exposure at specific locations. These limits are usually related to the use of the property the sound is entering. These ordinances set zoning performance standards for new noise sources. Noise zoning is then used by local authorities for land-use planning.

In the 1990s, the World Health Organization (WHO) published guideline target values to be adopted for protection against noise.^{3,4} The WHO recommended the following: (1) to protect the majority of people

from being moderately annoyed during the daytime, the outdoor A-weighted sound pressure level (L_{Aeq}) should not exceed 50 dB, (2) to protect the majority of people from being seriously annoyed during the daytime in outdoor living areas the A-weighted sound pressure level (L_{Aeq}) should not exceed 55 dB and (3) at nighttime outside sound pressure level should not exceed 45 dB in residential areas, so that the recommended A-weighted sound pressure level of 30 dB inside bedrooms with the windows open can be met. The WHO also suggests a limit of 60 dB for the maximum outdoor event A-weighted sound pressure level at night to protect people from sleep disruption.

These values were recommended in the European Green Paper on Future Noise Policy¹ as objective noise levels for all European Union (EU) member states. They have also been adopted in noise regulations in other parts of the world.⁵ New guidelines for the exposure to noise at night have been prepared recently by the WHO. A final draft was approved in late 2006, and a final publication is expected in 2007.

5 COMMUNITY NOISE ORDINANCE COMPONENTS

A community noise ordinance can be a precious instrument for dealing with noise at a local level. The quality and the quantity of the overall noise are addressed, noisy activities are regulated, noise limits are set, and responsible bodies and cost-effective noise abatement policies are defined. It must first be determined, however, whether the local government concerned has enough authority to legislate on the noise matters, since its powers are delegated powers and its legislative authority is only that granted by statutory or constitutional provisions.

A well-written noise ordinance must cover a number of components in a concise, clear, and precise way so as to address the local noise issues in as comprehensive a manner as possible to avoid misinterpretation and litigation. Vagueness, indefiniteness, and uncertainty should be prevented.

A community noise ordinance starts by a declaration of policy, a comprehensive list of definitions of terms and technical references, and by establishing the powers and duties of the municipal agency or department having the lead responsibility for the ordinance (noise control officer).

The rating index and its assessment method must be very clearly defined. The metrics most widely used is the long-term A-weighted continuous equivalent sound pressure level, L_{Aeq} , since it yields a good correlation with noise effects.⁶ The day-night average noise level, L_{dn} , is a 24-h A-weighted noise index used in the United States. It is calculated from the values of L_{Aeq} during daytime and during nighttime where a 10-dB penalty is applied to sound occurring between 10 p.m. and 7 a.m. The European Directive 2002/49/EC introduced the 24-h day-evening-night level, L_{den} , also calculated from the values of L_{Aeq} during the day period, during the evening period with a penalty of 5 dB and during the night period with a penalty of 10 dB, to be used by all EU member states in strategic noise mapping and action plans.⁷ Other

indicators are used for the rating of road traffic noise or of aircraft noise in different countries. The ordinance must also refer to impulsive, narrow-band, or other relevant acoustical characteristics and establish any corresponding corrections to the rating index.

Measurement and calculation procedures are required to follow the applying standards. The recommendations and provisions set out in the International Organization for Standardization (ISO) 1996 standard⁸ or equivalent [e.g., American National Standards Institute (ANSI)] are usual requisites. Noise assessment location (by measurement or calculation) and other relevant conditions (time intervals, emission or received noises) not covered by applying standards should be included in the text of the ordinance.

Reference time periods are defined, with their start and end hours clearly established, if not set at national level. Some countries consider only two reference periods, daytime and nighttime, whereas others consider a third one, a rest or evening period.

The noise ordinance usually defines noise zones according to the land uses and noise-sensitive activities. Corresponding noise limit values are stipulated for each reference time interval. The most stringent limits apply to residential, school, hospital, or leisure areas. It is recommended that different noise zones are created with noise limits in steps of 5 dB. Experiences with courser grades, with 10-dB steps, for example, have proved less practical and less effective.

Restrictions on noisy activities, musical instruments, and public address systems, construction, machine operation, traffic (e.g., heavy goods vehicles and aircraft) should be defined for the different noise-sensitive zones, together with criteria regarding the maximum permitted noise levels and the applicable hours. All such activities have to be clearly defined so as to avoid alternative interpretations and future litigation.

Restrictions are set for construction of some types of buildings (residence, school, hospital, or similar structure) and for land-use planning purposes so that the noise limits for each noise zone can be ensured. Similar types of restrictions are set for new outdoor or indoor recreational and leisure areas for the same reason. Plans for construction of new transportation systems or expansion of the capacity of existing ones in or near noise-sensitive zones may also be restricted, unless the necessary noise abatement measures are included to ensure that the noise levels in the zone will be within the prescribed limits.

The noise limits usually apply to the overall noise levels, but they may refer to noise from the different primary noise sources (industry, road traffic, railway traffic, and air traffic). Limits on noise emissions from machinery, construction work, and industry can be set since they can be well controlled at local level. These noisy activities are usually licensed by the municipalities. Limits on noise from transportation are usually set at the receiver. This is an area where coordination with transport authorities and with regulations at national level will prove most fruitful, given the limitations of the local legislative powers regarding

nationwide transport systems (e.g., airports, highways, and national railways).

Some restrictions (access traffic, activities) may have economic and societal prices, and the community should decide what level of cost-benefit is most appropriate. A number of experiences with severe traffic restrictions in some European cities have met with the opposition of residents who abandoned the area allegedly due to a decrease in economic activity and to the fear of a drop in real estate values.

Responsibilities for the measurement and assessment of noise should be set. Duties of the noise control agency or officer are defined to review the projects that may result in the production of sound, to inspect any place or situation suspected of violating any provision of the ordinance, and to investigate and pursue possible violations of the ordinance. Public education and information programs should be required or suggested. Participation of public-interest groups is mandatory in some countries and recommended in others. Noise mapping and noise action planning are usually required to integrate the land-use plans and long-term urban development plans where these instruments are operative.

Enforcement provisions must be clearly set out. The noise control officer or agency must rely on a well-trained team of municipal or county engineers who must be technically prepared and equipped to review relevant acoustical projects, to proceed with inspections, and to issue notices of violation and abatement orders (these are more effective if such orders include advice or recommendations on types of possible solutions or remedies). Although they do not need to be experts or even hold a college degree, some training on basic acoustics, sound radiation and propagation, and acoustical measurements should be provided to the technical staff. They must have a good knowledge of the existing measurement and calculation standards and of the measuring apparatus. The higher the quantitative nature of the ordinance, the higher is the technical requirement and the associated cost.

Fines and penalty actions must be well defined. The ordinance must state the explicit time criteria and goals for the full compliance of the regulations: hours of restrictions and periods of time to correct the violation or to implement the necessary remedies or abatement measures. Exceptions (e.g., emergencies) and variances (time to comply in specific conditions) should also be included.

The document *Model Community Noise Control Ordinance* issued by the U.S. Environmental Protection Agency (EPA) in the 1970s, describes a generic layout of a community noise ordinance to be adopted in U.S. communities.⁹ Model noise ordinances were thereafter drafted in various U.S. states (e.g., Alaska, California, and New Jersey) aimed at their municipalities.

The community may publish, as a support to the noise ordinance, technical and information guides on community noise with more detailed definitions, basic explanations on noise production, noise sources, and effects of noise on practical measures and procedures to reduce it and on how the citizens can seek abatement orders. This has been followed in many cities of various countries with great success. Information regarding

noise and noise effects is never too much but should be provided at a level that can be fully understood by the target population, meaning that different brochures or documents, technical and nontechnical, may be required. Community noise ordinances have been instruments for the management and control of noise in local communities of many countries worldwide.

6 THE U.S. NOISE POLICY

The need for a noise policy in the United States was first recognized in 1967. In 1969, the National Environmental Policy Act (NEPA) was approved.¹⁰ The NEPA is a basic national charter for protection of the environment in the United States. NEPA mandated the environmental impact assessment process, and noise is one of the many environmental attributes that must be considered.

In 1972, the Noise Control Act (NCA 72) was approved by the U.S. Congress.¹¹ The NCA 72 was passed specifically to address environmental noise. The NCA 72 stated that it is "the policy of the United States to promote an environment for all Americans free from noise that jeopardizes their health or welfare." In the act, the U.S. Congress recognized that the "primary responsibility for the control of noise rests with state and local governments" while "federal action is essential to deal with major noise sources."

The responsibility for implementing NCA 72 was assigned to the EPA.¹² This was to be the leading federal agency in charge of coordinating the programs of all federal agencies dealing with noise control. However, in the early 1980s EPA was no longer involved with noise control regulations.^{12,13} About a dozen federal agencies have since been responsible for the development, formulation and implementation of the U.S. noise policies together with the corresponding bodies of state and local authorities. The policies of these agencies have not always been coordinated, leading to some lack of consistency in noise requirements, which usually apply separately to different noise source emissions.¹⁴

The aircraft noise policy of the Federal Aviation Administration (FAA), applicable to civilian-operated airports, has been very effective. The Aircraft Noise Abatement Act of 1968 (later modified by the NCA 72) directed the FAA to establish standards and regulations for aircraft noise.¹⁵ Aircraft noise certification by FAA was required by the 1969 Federal Aviation Regulations.¹⁶ This was followed by the 1976 Aviation Noise Abatement Policy¹⁷ and by the Aviation Safety and Noise Abatement Act of 1979.¹⁸ In 2000, the Aviation Noise Abatement Policy was revised and various issues from aviation noise assessment to promotion of compatible uses of impacted land were outlined. The FAA and the Department of Defense adopted the annual A-weighted day-night average sound pressure level of 65 dB as the level for action regarding aircraft noise abatement in residential areas near an airport.¹⁹

Road traffic noise has been regulated by the Federal Highway Administration (FHWA) since it was mandated by the Highway Federal Act of 1970 to develop noise standards for mitigating highway traffic

noise and by the NCA 72 to enforce the noise emission standards for vehicles that were to be defined by the EPA. A number of documents were published since the 1970s. The Procedures for Abatement of Highway Traffic Noise and Construction Noise set limits for levels of noise along highways and defined criteria and the responsible bodies for noise abatement procedures.²⁰ The FHWA criterion for action to protect residents near a federally funded highway project is the noise action level of 67 dB corresponding to the peak traffic hour L_{Aeq1h} . Land-use planning near highways is, however, left to state and local governments.

The U.S. EPA recommended in 1974 that the outdoor A-weighted day-night sound pressure level should be kept below 55 dB in residential areas. This value has also been adopted by the Federal Energy Regulatory Commission (FERC) to protect residents near some industrial installations.

The policy for noise protection is now basically defined at state or local level since it was recognized as a more efficient approach. Nevertheless, for communities impacted by a combination of different sources, the issue is a difficult one since a variety of limits and metrics apply. A large number of U.S. cities and towns have their own community noise ordinances.²¹ The first known local noise ordinance regarding noise limits was adopted by Chicago around 1955. These were zoning regulations aimed primarily at industry and targeted at 61 dB for sound entering other business areas and 54 dB for sound entering residential areas during day or night. The New York City noise ordinance is currently undergoing a major revision. Most community noise ordinances in the United States now apply the general strategy set out in the EPA's Framework for Community-Based Environmental Protection.²²

The need to revise the U. S. national noise policy is now being considered seriously.^{13,14,23,24} There is a need to unify noise protection criteria at the national level and to reactivate a lead agency responsible for noise policy and control. A reformulation of the U.S. noise policy can be expected in the near future.²¹

7 THE EUROPEAN CHALLENGE

Noise regulations were passed in many European countries and cities since the late 1970s. They dealt with different aspects of noise from transportation, equipment, neighborhood, or leisure activities. Most defined noise-sensitive zones, depending on the different land uses, defined associated noise limits for day and for night periods, and established restrictions on traffic and on noise-producing activities.

Environmental noise is addressed at the European level through a wide range of instruments.²⁵ Various directives regarding noise emissions from different sources, such as motor vehicles, railway systems, aircraft, household appliances, and outdoor machinery, have been approved since the early 1970s.

Directive 86/594/EEC was passed in 1986 regarding noise labeling of household appliances.²⁶ Directive 2000/14/EC lays down noise provisions to reduce the noise emitted by outdoor equipment and requirements for harmonization of noise emission limits and standards,

of conformity assessment procedures, and of noise level marking.²⁷ Directive 2003/44/EC, which amends the previous recreational craft Directive 94/25/EC and took effect progressively from 2005, establishes requirements regarding noise emission limit values for recreational craft.²⁸

The directives on noise emission from new motor vehicles have been a success story. The first European harmonized noise requirements for road vehicles were introduced in 1970 by Directive 70/157/EEC relating to the permissible noise level and the exhaust system of four-wheel motor vehicles.²⁹ Noise limits for new cars first defined in Directive 77/212/EEC were made increasingly more stringent until the most recent one, 92/97/EEC.²⁹ The decrease in the prescribed maximum allowed noise levels ranged from 6 dB for passenger cars to 10 dB for heavy trucks. Directive 97/24/EC³⁰ sets permissible noise levels for two- and three-wheel vehicles and their exhaust systems, and Directive 2001/43/EC³¹ deals with tire rolling noise.

European legislation has addressed railway noise at source through directives on railway interoperability for high-speed rail (Directive 96/48/EC³²) and for conventional rail (Directive 2001/16/EC³³). Technical specifications were approved in 2002, setting out noise emission limits for high-speed trains at different speeds.

Noise emission limitations from civil aircraft have been in force since 1980 (Directive 80/51/EEC.³⁴) Directive 92/14/EEC of 1992, based on standards of the International Civil Aviation Organization (ICAO), banned the noisiest aircraft (Chapter 2 of Annex 16 of ICAO) from European airports.³⁵ In 2002, Directive 2002/30/EC established rules and procedures with respect to the introduction of noise-related operating restrictions at EU airports.³⁶ It further required that results of the implementation of this directive be reported no later than 2007.

In the mid-1990s various studies were conducted as a starting point of a new directive on environmental noise. It was found³⁷ that about 20% of the European population was exposed to A-weighted sound pressure levels of 65 dB or above, mainly from transportation. In 1996, the European Commission produced the Green Paper on Future Noise Policy.¹ Following the publication of this document, a new framework for noise policy, based on shared responsibility between the European Union, national, and local authorities was defined.

The Environmental Noise Directive (END) 2002/49/EC was published in 2002 on the basis of the Green Paper recommendations to address noise issues and to define a "common approach for all European countries in order to avoid, prevent or reduce on a prioritized basis the harmful effects, including annoyance, due to exposure to environmental noise".⁷ The END defines the basic principles of a harmonized European noise policy. It requires the assessment of the environmental noise, both overall and from major noise sources, such as transportation and industry, the number of people exposed to different noise levels, action plans for reduction of noise

exposure, communication with the public, and communication between the European Commission and the member states. No noise limits were included as this is left to each country or local community.

A noise expert network was set up in order to assist and provide advice to the European Commission prior to and after the publication of the END. Different working groups of experts from different member states were created to deal with emissions from noise sources and with noise effects and perception. Two working groups still meet regularly: Assessment of Exposure to Noise (WG-AEN) and Health and Socio-Economic Aspects (WG-HSEA).

The European Directive 2002/49/EC requires the competent authorities to draw strategic noise maps for the assessment of noise from major transport infrastructures and in communities with more than 100,000 inhabitants.⁷ Action plans are required and should be designed to manage noise issues and effects, including noise reduction, if necessary. Two stages are defined. In the first stage, strategic noise maps for all agglomerations with more than 250,000 inhabitants, major airports with more than 50,000 movements per year, major roads with more than 6,000,000 vehicles per year, and railways with more than 60,000 passages per year must be completed by June 2007. The corresponding action plans must be finished by July 2008. The second stage corresponds to other agglomerations with more than 100,000 inhabitants, major roads with more than 3,000,000 vehicles per year, and railways with more than 30,000 passages per year. Strategic noise maps must be completed by June 2012 and action plans by July 2013. Noise maps and action plans are to be reviewed every 5 years.

All EU directives are transposed into national legislations of the European member states. Their own noise ordinances at national, regional, or municipal levels that address noise zoning, noise limits, and noise abatement³⁸ incorporate the growing harmonized noise criteria and procedures.

8 THE EXPERIENCE IN JAPAN

Environmental noise policies in Japan started in 1967, and in 1968 the first Noise Regulation Law was approved and later amended in 1995 and in 2000.³⁹ The Environmental Quality Standards for Noise⁴⁰ were first defined in May 1971, based on Article 9 of the Basic Law for Environmental Pollution Control. Limit noise values were stipulated for two types of areas: general areas and roadside areas. General limits for the A-weighted sound pressure level were established at 35 dB during nighttime for quiet neighborhoods and at 60 dB during daytime for areas with a considerable number of dwellings but which included commerce and industrial uses. Limits for roadside areas were 5 to 10 dB higher depending on various factors such as the number of road lanes. In accordance with the provisions of Article 16 of the Basic Environment Law (Law No. 91) of 1993, the noise limits were reviewed in 1998 and enforced in 1999.⁴¹ Outdoor noise limits of 55 dB during daytime and of 45 dB during nighttime for residential areas

were then recommended. For areas with particularly noise-sensitive uses, the limits are 5 dB lower, whereas for areas with commerce and industry they are 5 dB higher. In areas facing roads with two or more lanes, another 5 dB were allowed.

The Noise Regulation Law required the local governments to proceed with noise zoning and classification. By the mid-1990s, more than 600 large cities and more than 850 small municipalities had their own noise ordinances.⁴² That law also demanded the Environment Agency to establish the maximum permissible levels of noise produced by the operation of motor vehicles. Since they were first implemented in 1971, controls of running noise on new vehicles have been strengthened several times, namely in 1979, in 1986, and in 1992 when the document *The Future Policy for Motor Vehicle Noise Reduction* was approved.

The Environmental Quality Standards for Aircraft Noise were initially defined in 1973 and later revised and updated in 1993 to prevent aircraft noise pollution.⁴³ Maximum levels of the A-weighted equivalent continuous perceived noise level (WECPNL) (calculated from $WECPNL = L_{Apeak} + 10 \log N - 27$ where L_{Apeak} is the mean level of all peaks that exceed the background noise by at least 10 dB in one day, and N is a time-weighted total number of aircraft) are prescribed as 70 dB for residential areas and 75 dB for other areas where normal living conditions should be preserved. A certification system banning the operation of aircraft whose noise exceeds prescribed levels has been in effect since 1975 and later strengthened in 1978, leading to the phasing out of the noisier aircraft at major airports as from 1988. In order to implement further aircraft noise countermeasures, a portion of the Civil Aeronautics Law was revised in 1994 pointing to the gradual restriction of operation of the noisier aircraft in Japan from 1995 and to their prohibition as from 2002.

Noise from the Shinkansen railway line is the subject of the Environmental Quality Standards for Shinkansen Superexpress Railway Noise, as originally issued in 1975 and revised and updated in 1993.⁴⁴ Noise limits are 70 dB for residential areas and 75 dB for areas with commerce and industry where normal living conditions should be preserved, measured as A-weighted peak sound pressure levels. These limits actually relate to noise emissions but not to the exposure of the population to noise since the number of trains is not accounted for. For conventional railway trains, noise standards have been under study.

Based on the noise standards, countermeasures have been implemented against all types of noise sources. Local government actions deriving from local community noise ordinances have been reportedly very effective. However, it has been recognized that the whole noise policy needs to be reconsidered and this seems to be underway.

9 THE AUSTRALIAN EXPERIENCE

In Australia, excessive noise is regulated in each state by environment protection acts and by environment protection policies. The environment protection policies set maximum permissible noise levels for certain types

of machines during specified times as well as for motor vehicles and control the maximum levels of noise exposure in areas with residential uses. Local governments, as regulatory authorities, are demanded to enforce the noise limit values.

In South Australia, for example, the Environment Protection (Industrial Noise) Policy 1994 established maximum permissible noise levels for both day and night in six different land zones.⁴⁵ Daytime A-weighted sound pressure level limits are 47 dB for a rural area or 52 to 58 dB for urban residential areas, depending on other existing uses. The corresponding limits for nighttime are 40 dB and 45 to 50 dB. Maximum noise levels are also defined for premises adjoining roadways carrying more than 100 vehicles/hour ranging from 54 to 76 dB with corrections for the distances to the road.

In New South Wales, local environmental noise issues are managed by the Protection of the Environment Operations Act 1997⁴⁶ and by the Protection of the Environment Operations (Noise Control) Regulation 2000. This document prescribes maximum noise levels for different classes of motor vehicles with specifications for testing procedures. The Environmental Noise Criteria for Road Traffic Noise set out criteria to be applied to residential areas with maximum A-weighted sound pressure levels of 55 dB to 60 dB during the day or 50 dB to 55 dB during the night, depending on the type of road and on new or redevelopment area.⁴⁷

In Queensland, the Environmental Protection (Noise) Policy 1997, amended in 2003, prescribes rules for noise labeling of various products, for noise assessment to be used by the local authorities, and recommendations to get the communities involved in the protection of environmental noise.⁴⁸ Planning levels are defined. The A-weighted equivalent sound pressure levels in front of the most exposed facades of noise-sensitive buildings must not exceed 65 dB (87 dB maximum single event) near railways or 60 dB (80 dB maximum single event) near public roads. Near an airport, L_{max} must not exceed 70 dB.

10 OTHER EXPERIENCES

In Canada, provincial governments set their own noise policies. Ottawa's regulations are based on the Noise Control Guidelines of 1995.⁴⁹ The city new environmental plan prescribes maximum A-weighted sound pressure levels of 58 dB during the day and 53 dB during the night from roads, railways, or transitways. Criteria are established for the compatibility of land uses in the vicinity of airports. The Noise Control By-Law of the City of Vancouver of 1989, last amended in 2004, establishes noise limits for noise emissions in different noise zones. For a quiet zone, for example, the A-weighted sound pressure level limits vary between 55 dB and 60 dB during daytime and between 45 dB and 55 dB during nighttime, depending on from where the noise is emitted.⁵⁰

In China, the first act concerned with noise was the National Environment Protection Act of 1979.⁵¹ The Regulations on Prevention and Control of Environmental Noise were approved in 1989 and updated in 1996. Local governments were made responsible for the implementation of noise requirements. Maximum

noise emission levels for motor vehicles were approved in 1979. Other criteria and standards were defined together with noise zoning where noise limits were established for day and for night in 1993. Residential area A-weighted sound pressure level limits are 55 dB during daytime and 45 dB during the night. For quiet residential areas, the limits are 5 dB lower, and for mixed areas they are 5 dB higher. The criteria are implemented by national and local authorities.

In Hong Kong, the Noise Control Ordinance 1988 (with later amendments) is the basic regulation.⁵² The Road Traffic Ordinance and the Civil Aviation (Aircraft Noise) Ordinance requires compliance with noise emission standards. New more stringent regulations have been under study.

In Brazil, the state of Rio de Janeiro approved in 2004 an ordinance on urban noise.⁵³ Of a qualitative nature, it demands the municipalities to implement noise assessment and noise abatement actions and sets the basis for a future environmental noise policy.

11 FINAL DISCUSSION

Community noise ordinances of different types have been promulgated in many cities and counties all over the world. They need to be coordinated and consistent with regulations at all other levels, namely regional and national, if an effective improvement in the quality of the sound environment is to be achieved. In a global policy, community noise ordinances act as self-regulation measures that are able to address noise at a local level in a way that citizens can be drawn closer to the actions and get more involved with their results.

Since much of the noise in a community is a local issue, local policies and actions can produce measurable results if a straightforward, practical, and economical approach is set up. Simply enacting a new noise ordinance, either of qualitative or quantitative nature, is not enough, though. The noise ordinance must address the noise problems in a clear and realistic way and must be reasonable. All technical issues such as metrics, standards, assessment, and inspection procedures must be well defined. Responsible bodies must be established together with their obligations and powers, ensuring a capable supervision and enforcement. Efficient enforcement measures and the allocation of adequate financial and technical resources are key issues for successful results. The provision of guides to help on the technical issues and of rules for dissemination of information has generally proved to be an advisable feature.

The maximum permitted noise levels defined in noise zoning for daytime and for nighttime in recent years are generally very close to those recommended by the WHO, in most cases referred to the A-weighted continuous equivalent sound pressure level.

Community noise ordinances and national noise policies are currently being revised in many parts of the world, generally incorporating more stringent noise limits and criteria. Although a reduction in noise emissions from road vehicles and aircraft has been achieved due to successful policies in the United States, Europe and Japan, for example, a corresponding reduction in receiver noise values has not been so

apparent given the rise in traffic.⁵⁴ The trend in the increase of population density in urban areas must be met with the growing citizen's requirements for a better quality of life. Community noise criteria and goals must be used as tools in land-use and transport planning.⁵⁵ Experience has shown that noise ordinances play a primary role in the community noise management and control policy.

GLOSSARY

A-weighted sound exposure *See* Sound exposure.

Absorption Conversion of sound energy into another form of energy, usually heat, when passing through an acoustical medium or at a boundary.

Absorption area *See* Equivalent sound absorption area.

Absorption factor, absorption coefficient, absorbance Ratio of the dissipated and transmitted sound power to the incident sound power. In a specified frequency band, the absorption factor is a measure of the absorptive property of a material or surface. Also known as (*sound*) *absorption coefficient*. Unit: none. Symbol: α . *See* Dissipation factor, Transmission factor, Reflection factor. *Note:* (1) The absorption factor equals the dissipation factor plus the transmission factor, $\alpha = \delta + \tau$, where δ is the dissipation factor, and τ is the transmission factor. (2) The summation of the dissipation, transmission, and reflection factors is unity, $\delta + \tau + r = 1$, where r is the reflection factor.

Accelerance A form of the frequency response function, which is the complex ratio of the acceleration to the excitation force. Units: (metre per square second) per newton [$(\text{m/s}^2)/\text{N} = \text{kg}^{-1}$]. *See* Compliance, Mobility, Dynamic Mass. *Note:* The alternative term *inertance* is not recommended because it has a conflicting interpretation. Sometimes inertance is referred to as the reciprocal of accelerance.

Acceleration A vector quantity equal to the rate of change of velocity. Units: metre per square second (m/s^2). *See* Displacement, Velocity, Jerk.

Accelerometer A transducer whose electrical output is proportional to acceleration in a specified frequency range.

Acoustical holography An inspection method using the phase interference between sound waves from an object and a reference signal to obtain an image of reflectors in the object under test.

Acoustical trauma Ear injury caused by a sudden and intense sound pressure that causes a degree of permanent or temporary hearing loss.

Acoustic impedance At a specified surface, the complex ratio of the average sound pressure over that surface to the sound volume flow rate through that surface. Units: pascal per (cubic metre per unit time) [$\text{Pa}/(\text{m}^3/\text{s})$]. Symbol: Z_a . *See* Characteristic impedance, Mechanical impedance, Specific acoustic impedance. **Acoustic reactance** Imaginary part of acoustic impedance. Symbol: R_a . **Acoustic resistance** Real part of acoustic impedance. Symbol: X_a .

Acoustic reactance *See* Acoustic impedance.

Acoustic resistance *See* Acoustic impedance.

Acoustics Science of the production, control, transmission, reception, and effects of sound and of the phenomena of hearing.

Action level The cumulative work shift noise dose at which hearing conservation program is mandated by the Occupational Safety and Health Administration (OSHA). An 8-hour time-weighted average of 85 dB measured with A-weighting and slow response, or equivalently, a dose of 50 percent. *See* Hearing conservation Program, Noise dose.

Active control Of sound and vibration, the use of secondary sources of excitation to cancel, or reduce, the response of a system to given prime sources; also to suppress self-excitation oscillations of a system that is unstable.

Active sound control *See* Active control.

Active sound field A sound field in which the particle velocity is in phase with the sound pressure. All acoustic energy is transmitted; none is stored. A plane wave propagating in free field is an example of a purely active sound field.

Active vibration control *See* Active control.

Admittance The reciprocal of an impedance. *See* Acoustic impedance, Characteristic impedance, Mechanical impedance, Mobility.

Airborne sound Sound that propagates through air. *See* Liquid-borne sound, Structure-borne sound.

Airflow resistance A quantity defined by $R = \Delta p / q_v$, where Δp is the air pressure difference, in pascals, across the test specimen; q_v is the volumetric airflow rate, in cubic metres per second, passing through the test specimen. Units: pascal second per cubic metre ($\text{Pa}\cdot\text{s}/\text{m}^3$). Symbol: R . *See* Specific airflow resistance.

Airflow resistivity If the material is considered as being homogenous, a quantity defined by $r = R_s / d$, where R_s is the specific airflow resistance, in pascal seconds per metre, of the test specimen;

d is the thickness, in metres, of the test specimen in the direction of flow. Units: pascal second per square metre (Pa·s/m²). Symbol: r . *See* Specific airflow resistance.

Aliasing error An error in digital signal processing in which high-frequency signal energy is folded into lower frequency components due to inadequate sampling frequency that is less than twice the maximum frequency in the signal. *See* Sampling theorem, Antialiasing filter.

Alignment The fact of being in line or bringing into line. For rotating machinery, alignment refers to the axial continuity of machine components, such as shaft and bearings, during operation.

Ambient noise (1) Sound present in a given situation at a given time, in absence of that from sources of immediate concern, usually being composed of sound from many sources near and far. *See* Background noise. (2) In underwater acoustics, the naturally occurring acoustical environment in the ocean, caused by wave breaking, marine life, and other sources. (3) In sonar detection, the noise from all unwanted sources of sound, apart from those directly associated with the sonar equipment and the platform on which it is mounted.

Amplitude distribution A method of representing the amplitude (or level) variation of noise by indicating the percentage of time that the noise level occurs in a series of amplitude intervals.

Analog-to-digital conversion (ADC) The process of sampling an analog signal to convert it to a series of quantized numbers, a series that is a digital representation of the same signal. The sampling frequency must be at least twice as high as the highest frequency present in the signal to prevent aliasing errors. *See* Aliasing error, Nyquist frequency, Sampling theorem.

Anechoic room A test room whose surfaces absorb essentially all of the incident sound energy over the frequency range of interest, thereby approximating free-field conditions over a measurement surface. *See* Semianechoic room, Free field.

Angular frequency Frequency of a periodic quantity in units of radians per unit time (rad/s). Symbol: ω . *See* Frequency.

Angular repetency *See* Wavenumber.

Annoyance A person's internal response to a noise. Is quantifiable (1) psychologically by rating or (2) technically by a physical noise descriptor, for example, the equivalent continuous A-weighted sound pressure level $L_{Aeq,T}$. For a given person, usually the correlation coefficient between descriptor and related ratings does not exceed 0.5 due to the influence of other factors in determining annoyance. *See* Noise, Rating, Equivalent continuous A-weighted sound pressure.

Antialiasing filter An analog low-pass filter applied to continuous analog signals prior to analog-to-digital conversion, to eliminate frequency components higher than one-half the sampling frequency (Nyquist frequency). *See* Aliasing error, Sampling theorem, Nyquist frequency.

Antiresonance A condition in forced vibration whereby a specific point has zero amplitude at a specific frequency of vibration. For a certain frequency response function (FRF), an antiresonance may correspond to a local minimum in the magnitude. For a point FRF, there must be an antiresonance between two resonances. However, different FRFs have different antiresonances. Some FRFs have no antiresonance. *See* Resonance.

Apparent sound reduction index *See* Sound reduction index.

Argand diagram A plot of a complex function in which the x and y coordinates denote the real and imaginary parts of the function. *See* Frequency response function, Nyquist diagram.

Articulation index (AI) A number that specifies the output intelligibility of a speech transmission channel, based on the signal-to-noise ratio at the listener. The articulation index takes values between zero (completely unintelligible) and unity (completely intelligible). *See* Intelligibility, Signal-to-noise ratio, Privacy index.

Articulator Any of the moveable parts in and around the vocal tract that can affect its shape, and therefore, the speech sounds generated. The tongue is the most important articulator; lips, teeth, and velum are others. *See* Vocal tract, Articulatory.

Articulatory An articulatory model or synthesizer uses parameters related to properties of the articulators: for example, position of tongue tip or tongue dorsum, degree of lip rounding, or length of the vocal tract. *See* Articulator.

Attenuation coefficient Coefficient α in the spatial attenuation factor $e^{-\alpha x}$, which describes the amplitude reduction of a single-frequency progressive wave with distance x , in the propagation direction. Unit: reciprocal metre (m⁻¹). Symbol: α . *Note:* the quantity $1/\alpha$ is called the *attenuation length*, and $m = 2\alpha$ is called the *power attenuation coefficient*.

Audibility threshold The lowest sound pressure level, at a specified frequency, at which persons with normal hearing can hear. Sometimes also known as *hearing threshold*. *See* Hearing threshold.

Audio frequency Frequency of a sound in the range normally audible to humans. Unit: hertz (Hz). Audio frequencies range roughly from 20 Hz to 20 kHz.

Autocorrelation Function A statistical measure of the extent to which one part of a signal is related to

another part, offset by a given time, of the same signal. The Fourier transform of the autocorrelation function gives the autospectrum. *See* Cross-correlation function, Power spectrum.

Autospectrum Also known as *autospectral function, power spectrum*. *See* Power spectrum, Cross spectrum.

A-weighted sound power level *See* Sound power level.

A-weighted sound pressure level *See* Sound pressure level.

Background noise (1) Total of all interference from unwanted sound, independent of the sound source being studied. *See* Ambient noise. (2) Undesired signals that are always present in electrical or other systems, independent of whether or not the desired signal is present. Background noise may include contributions from airborne sound, structure-borne vibration, and electrical noise in instrumentation. *Note* According to ANSI S1.1 - 1994, ambient noise detected, measured, and recorded with the signal is part of the background noise.

Balancing The procedure of adjusting the mass distribution of a rotor to reduce the transverse vibration of the rotor.

Band pressure level *See* Sound pressure level.

Bandwidth (1) The difference between the upper and lower frequency limits of a frequency band. (2) Of a signal, the range of frequencies between the upper and lower frequency limits within which most of the signal energy is contained. (3) Of a linear system or transducer, the range of frequencies over which the system is designed to operate. (4) Of a bandpass filter, the difference in frequency between the upper and lower cutoff frequencies. *See* Critical bandwidth, Effective noise bandwidth, Half-power bandwidth.

Bearing A device that supports, guides, and reduces the friction of motion between fixed and moving machine parts. There are primarily two types, rolling-element bearings and fluid-film bearings. A rolling-element bearing consists of an inner race, an outer race, balls or rollers, and a cage to maintain the proper separation of the rolling elements. A fluid-film bearing supports the shaft on a thin film of oil or on a thin film of pressurized air. **Bearing misalignment** Misalignment that results when the bearings supporting a shaft are not aligned with each other. The bearings may not be mounted in parallel planes, cocked relative to the shaft, or distorted due to foundation settling or thermal growth.

Beat A phenomenon of slow amplitude modulation produced by interference between two simple harmonic signals, when the frequency difference is a small fraction of either frequency. **Beat frequency** The frequency of the amplitude modulation, equal to

the difference in frequency between the two original signals.

Bel (B) Unit of level in terms of logarithm to base 10, abbreviated as B. *See* Level, Decibel.

Bode diagram, Bode plot (1) A form of presentation of a complex function, such as a frequency response function, in two plots. One plot shows the magnitude of the complex function against frequency, plotted in decibels. The other plot shows the phase of the complex function against frequency. Both plots use the same logarithmic frequency scale on the horizontal axis. *See* Frequency response function, Argand diagram, Nyquist diagram. (2) Specifically for rotating machines, a pair of two plots displaying the magnitude and phase of a particular order component of a vibration vector. Both plots are in Cartesian format and use the same horizontal axis, which represents rotational speed or perturbation frequency. *See* Order analysis.

Boundary element method A numerical approach for solving a boundary integral equation in which the domain of integral is divided into subdomains referred to as elements. An advantage of the boundary element method is the reduction of dimensionality. The wave equation in a three-dimensional region can be rewritten as boundary integral equation on a two-dimensional surface. Unlike the finite element method, the boundary element method is based on the Green's function, which satisfies the governing differential equation exactly over the domain and solves the unknown nodal values that approximately satisfy the boundary conditions. *See* Finite element method.

Bulk modulus Of a fluid or solid, the slope of the curve of pressure plotted against the logarithm of the density, with either adiabatic or isothermal conditions imposed.

Center frequency The arithmetic center of a constant bandwidth filter or the geometric center (midpoint on a logarithmic scale) of a constant percentage filter. *See* Constant bandwidth filter, Constant percentage filter.

Cepstrum For a real signal, a nonlinear signal processing technique that involves the inverse Fourier transform of the logarithm of the power spectrum or the Fourier transform of the signal. Since both the Fourier transform and the inverse Fourier transform are complex processes, the cepstrum is complex if the phase information is preserved. The complex cepstrum has the corresponding inverse complex cepstrum. However, if the input of the inverse Fourier transform is real, for example, the power spectrum, or the magnitude of the Fourier transform of the signal, the cepstrum is real. Exact definitions vary across the literature.

Characteristic equation (1) Any equation that has a solution, subject to specified boundary conditions, only when a parameter occurring in it has certain

values. (2) Specifically, the equation $A\mathbf{u} = \lambda\mathbf{u}$, which can have a solution only when the parameter λ has certain values, where A can be a square matrix that multiplies the vector \mathbf{u} , or a linear differential or integral operator that operates on the function \mathbf{u} , or in general, any linear operator operating on the vector \mathbf{u} in a finite or infinite dimensional vector space. Also known as *eigenvalue equation*. (3) An equation that sets the characteristic polynomial of a given linear transformation on a finite dimensional vector space, or of its matrix representation, equal to zero. *See* Eigenvalue, Eigenvector.

Characteristic impedance Of a medium, at a point and for a plane progressive wave, the magnitude of the ratio of the sound pressure to the component of the sound particle velocity, in the direction of the wave propagation. Characteristic impedance is defined by $Z_c = \rho c$, where ρ is the density, in kilograms per cubic metre; c is the (phase) speed of sound, in metres per second. Units: pascal per metre per second [Pa/(m/s)]. Symbol: Z_c . *See* Acoustic impedance, Specific acoustic impedance, Mechanical impedance.

Charge amplifier An amplifier with a low input impedance whose output voltage is proportional to the output charge from a piezoelectric transducer.

Close-proximity (CPX) method A measurement method used for measuring noise properties of tires and/or road surfaces (pavements), utilizing either a trailer with a test tire or a regular vehicle such as an automobile, SUV, or van on which one of its tires constitutes the test tire. Generally, at least two microphones are placed close to the test tire. In case of a trailer, the test tire is often covered by an enclosure that protects the tire and the microphones from noise from other vehicles and from air turbulence noise. Attempts to standardize this procedure and to specify a couple of reference tires for the CPX method are made within the ISO as part of the ISO 11819 series of standards. *See* Tire/road noise, Statistical pass-by method.

Coherence function Of two time signals, a measure of the degree to which the two signals are linearly related at any given frequency. The coherence function takes values between zero and unity.

Coincidence effect For a panel or partition, a great reduction of the sound reduction index as a function of frequency when the trace wave speed (speed at which the incident wave propagates along the panel) and the speed of the flexural wave in the panel are the same. *See* Sound reduction index.

Compliance (1) The reciprocal of stiffness. Sometimes also known as *flexibility*. (2) A form of the frequency response function: the complex ratio of the displacement to the excitation force. Also known as *dynamic compliance*, or *receptance*. *See* Accelerance, Mobility.

Condensation In acoustics, the increase in the density of a material under stress, divided by the original density. *See* Density.

Conductance Real part of an admittance. *See* Admittance, Susceptance.

Conductive hearing loss *See* Hearing loss.

Constant bandwidth filter A filter that has a fixed-frequency bandwidth, regardless of center frequency.

Constant percentage filter A filter whose bandwidth is a fixed percentage of center frequency, for example, octave filter.

Correlation coefficient (1) Of two real signals, $x(t)$ and $y(t)$, that are joint stationary with respect to time, the value of the covariance function at zero time delay $C_{xy}(0)$, normalized by the standard deviations of the two signals, σ_x and σ_y :

$$\rho_{xy} = \frac{C_{xy}(0)}{\sigma_x \sigma_y}.$$

See Cross-correlation coefficient. (2) Of two random variables X and Y , the normalized covariance, defined by

$$\rho_{XY} = \frac{\text{cov}(X, Y)}{\sigma_X \sigma_Y}.$$

Critical bandwidth The widest frequency band within which the perceived loudness of a band of continuously distributed random noise of constant bandwidth sound pressure level is independent of its bandwidth.

Critical frequency, critical coincidence frequency Of a panel or partition, the lowest frequency at which the coincidence effect occurs. If the panel is orthotropic or anisotropic, the critical frequency may vary with direction along the panel. Unit: hertz (Hz). Symbol: f_c . *See* Coincidence effect.

Critical speed Rotational speed of a rotating system that corresponds to a resonance frequency of that same system.

Cross-correlation coefficient Of two real signals that are joint stationary with respect to time, the normalized covariance function, defined by

$$\rho_{xy} = \frac{C_{xy}(\tau)}{\sigma_x \sigma_y}$$

where $C_{xy}(\tau)$ is the covariance function of the two signals $x(t)$ and $y(t)$, evaluated at time delay τ , and σ_x and σ_y are the respective standard deviations. *See* Correlation coefficient.

Cross-correlation function The statistical correlation between two different signals as a function of relative time between the signals. The Fourier transform of

the cross-correlation function gives the cross spectrum. See Autocorrelation function, Cross spectrum.

Cross spectrum, cross-power spectrum A complex spectrum containing the product of the power spectra of two correlated signals. The Fourier transform of the cross-correlation function. If the two time signals are $x(t)$ and $y(t)$, then the cross spectrum is $G_{xy}(i\omega) = X^*(i\omega)Y(i\omega)$, where $*$ denotes complex conjugate. The cross spectrum is conjugate even. See Cross-correlation function, Power spectrum.

Cumulative distribution A method of representing time-varying noise by indicating the percentage of time that the noise level is present above (or below) a series of amplitude levels.

Damped natural frequency Frequency of free vibration of a damped linear system. Unit: hertz (Hz). See Natural frequency.

Damping (1) Any means of dissipating vibration energy within a vibrating system to reduce the amplitude of movement, or to shorten the decay time of free vibration. (2) Of an enclosure, removal of echoes and reverberation by the use of sound-absorbing materials. Also known as *sound proofing*. **Coulomb damping** Dissipation of energy that occurs when the motion of a vibrating system is resisted by a force whose magnitude is constant and independent of displacement and velocity, and whose direction is opposite to the direction of the velocity of the system. Also known as *dry friction damping*. **Critical damping** The minimum viscous damping that will allow a displaced system to return to its original position without oscillation. **Damping ratio** For a system with viscous damping, the ratio of viscous damping to critical damping. **Hysteretic damping, hysteresis damping** Damping of a vibrating due to energy dissipation through mechanical hysteresis. The area of the hysteresis loop is a measure of damping. Also sometimes called *structural damping*. **Viscous damping** Dissipation of energy that occurs when the motion of a vibrating system is resisted by a force that has a magnitude proportional to the magnitude of the velocity of the system and direction opposite to the direction of the velocity of the system. **Structural damping** An equivalent term for *hysteretic damping*.

Day average sound pressure level Time-average sound pressure level between 0700 and 2200 hours (15 hours). Unit: decibel (dB). Symbol: L_d . See Time-average sound pressure level, Day-night average sound pressure level.

Day-night average sound pressure level The 24-hour time-average sound pressure level for a given day, after addition of 10 dB to night levels from between 2200 and 0700 hours. Unit: decibel (dB). Symbol: L_{dn} . See Time-average sound pressure level, Day average sound pressure level.

Decade A unit of logarithmic frequency interval from f_1 to f_2 , defined as $\log_{10}(f_2/f_1)$. 1 decade = 3.322 octaves. See Octave.

Decibel (dB) The unit of measure for powerlike quantities in acoustics, noise, and vibration to denote level and level difference where the base of the logarithm is $10^{1/10}$. Abbreviated as dB. One tenth of a Bel. One decibel is equal to the ratio $10^{1/10} = 1.26$. Multiplying powerlike quantities (such as sound power or mean square sound pressure) by the factor $10^{n/10}$ increases the level by n decibels. **Decibel scale** A linear numbering scale used to define a logarithmic amplitude scale, in units of decibels, thereby compressing a wide range of amplitude values to a small set of numbers.

Degrees of freedom The minimum number of independent coordinates required to define completely the positions of all parts of a mechanical system at any instant of time.

Density In continuum mechanics, the mass per unit volume of a material. Also known as *mass density*. Units: kilograms per cubic metre (kg/m^3).

Diffraction A phenomenon by which the propagation direction and intensity of a sound wave are changed when it passes by an obstacle or through an aperture if the wavelength of the sound wave is the same size or greater than the size of the obstacle or aperture.

Diffuse field An idealized sound field in which the sound pressure level is the same everywhere and the flow of energy is equally probable in all directions.

Diffuse sound Sound that is completely random in phase; sound that appears to arrive uniformly from all directions.

Dipole An idealized sound source consisting of two closely spaced out-of-phase monopoles. See Monopole, Quadrupole.

Directivity factor (1) Of a sound source, the ratio of the far-field mean-square pressure at a given frequency and radius, in a specified direction from the source, to the average mean square pressure over a sphere of the same radius, centered on the source. (2) The ratio of the mean-square pressure (or intensity) on the axis of a transducer, at a certain distance, to the mean-square pressure (or intensity) that a monopole source radiating the same power would produce at that point.

Directivity index A measure of the extent to which a source radiates sound predominantly in one direction. The directivity index, DI_i , in the direction from a source to microphone position i , is defined as $DI_i = L_{pi}^* - \overline{L_p^*}$, where L_{pi}^* is the sound pressure level at microphone position i , corrected for background noise, $\overline{L_p^*}$ is the sound pressure level averaged over the measurement surface, corrected for background noise. Unit: decibel (dB). Symbol: DI.

Discrete Fourier transform (DFT) A version of the Fourier transform applicable to a finite number of discrete samples. For a discrete sequence $x[n]$, its

discrete Fourier transform is

$$X[k] = \sum_{n=0}^N x[n] e^{-j(2\pi kn/N)}.$$

$X[k]$ is also discrete and has the same number of samples as does $x[n]$. The original sequence can be recovered from the inverse DFT:

$$x[n] = \frac{1}{N} \sum_{k=0}^N X[k] e^{j(2\pi kn/N)}$$

See Fourier transform, Fast Fourier transform.

Displacement A vector quantity that specifies the change of position of a body, usually measured from the rest or equilibrium position. Unit: metre (m). See Velocity, Acceleration, Jerk.

Dissipation factor, dissipation Ratio of the dissipated sound power to the incident sound power. Unit: none. Symbol: δ . See Absorption factor, Reflection factor, Transmission factor.

Doppler effect Phenomenon evidenced by the shift in the observed frequency from the source frequency caused by relative motion between the source and the observer. The Doppler effect is described quantitatively by

$$f_r = f_s \frac{1 + v_r/c}{1 - v_s/c}$$

where f_r is the received frequency, in Hz; f_s is the source frequency, in Hz; v_r is the component of velocity relative to the medium of the receiving point toward source, in metres per second; v_s is the component of velocity relative to the medium of the source toward the receiving point, in metres per second; c is (phase) speed of sound in a stationary medium, in metres per second.

Dose See Noise dose.

Dosimeter(s) Noise dosimeters measure and store sound pressure levels (SPL) and, by integrating these measurements over time, provide a cumulative noise exposure reading for a given period. Dosimeters may also provide a time history of sound exposure that is useful in determining contributions to the cumulative noise exposure.

Duct silencer See Muffler.

Dynamic capability index Given by $L_d = \delta_{pI_0} - K$, where δ_{pI_0} is the pressure-residual intensity index, K is selected according to the grade of accuracy required (see the table below). Unit: decibel (dB). Symbol: L_d . See Pressure-residual intensity index.

Bias Error Factor, K

Grade of Accuracy	Bias Error Factor (dB)
Precision (grade 1)	10
Engineering (grade 2)	10
Survey (grade 3)	7

Dynamic mass Ratio of applied force amplitude to resulting acceleration amplitude during simple harmonic motion. Reciprocal of accelerance magnitude. See Accelerance.

Dynamic modulus Ratio of stress to strain under vibratory conditions. Generally a complex quantity.

Dynamic range (1) Of a transducer, the ratio of the highest to the lowest input quantities within the linear range of the transducer, expressed in decibels. Unit: decibel (dB). (2) Of a spectrum analyzer, the maximum ratio of two signals simultaneously present at the input that can be measured to a specified accuracy, expressed in decibels. Unit: decibel (dB). (3) Of an acoustical variable, the ratio of the maximum and minimum mean-square values. Unit: decibel (dB).

Dynamic stiffness Of a point-excited mechanical system, the complex ratio of applied force to displacement. It is the reciprocal of dynamic compliance. Units: newton per metre (N/m). See Compliance.

Eccentricity Distance of the center of gravity of a revolving body from the axis of rotation.

Effective noise bandwidth Bandwidth of an ideal filter that would pass the same amount of power from a white noise source as the filter described. Used to define bandwidth of one-third octave and octave filters.

Effective perceived noise level A complex rating used to certify aircraft types for flyover noise. Includes corrections for pure tones and for duration of the noise. If $L(t)$ denotes the tone-corrected perceived noise level as a function of time, the effective perceived noise (EPN) level is defined as

$$L_{EPN} = 10 \log_{10} \left[\frac{1}{t_{ref}} \int 10^{L/10} dt \right]$$

The reference time used for normalization is $t_{ref} = 10$ s. Unit: dB re $(20 \mu\text{Pa})^2 \cdot 10$ s. Symbol: L_{EPN} . See Noise Exposure forecast.

Eigenfrequency An alternative term for *natural frequency*. See: Natural frequency, Eigenvalue.

Eigenvalue (1) Scalar λ such that $T(v) = \lambda v$, where T is a linear operator on a vector space, and v is an eigenvector. Specifically, of a square matrix, any scalar λ such that the determinant of $\mathbf{A} - \lambda \mathbf{I}$ vanishes, where \mathbf{A} is the matrix concerned, and \mathbf{I} is the identity matrix of the same size. Also known as *characteristic number*, *characteristic root*, *characteristic value*. See Eigenvector. (2) Of an acoustical system, usually refers

to one of the values κ_n^2 ($n = 1, 2, 3, \dots$) for which the equation describing the acoustic pressure at a specified frequency, e.g., the Helmholtz equation $(\nabla^2 + \kappa^2)p = 0$, has a solution matching the boundary conditions. (3) Root of a characteristic equation. Specifically, in modal analysis, the eigenvalue of the characteristic equation of a dynamic system is related to the square of one of the natural frequencies of the system. *See* Characteristic equation, Modal analysis.

Eigenvector (1) Nonzero vector v whose direction is not changed by a given linear transformation T ; that is, $T(v) = \lambda v$ for some scalar λ . Also known as *characteristic vector*. *See* Eigenvalue. (2) Specifically, in modal analysis an eigenvector of the characteristic equation of a dynamic system refers to a mode shape of the system.

Equivalent continuous A-weighted sound pressure level Value of the A-weighted sound pressure level of a continuous, steady sound that, within a specified time interval T , has the same mean-square sound pressure as a sound under consideration whose level varies with time. It is given by

$$L_{\text{Aeq},T} = 10 \log_{10} \left[\frac{1}{t_2 - t_1} \int_{t_1}^{t_2} \frac{p_A^2(t)}{p_0^2} dt \right]$$

where $p_A(t)$ is the instantaneous A-weighted sound pressure of the sound signal, p_0 is the reference sound pressure (20 μPa). Unit: decibel (dB). Symbol: $L_{\text{Aeq},T}$. *See* Equivalent continuous sound pressure level, Sound pressure.

Equivalent continuous sound pressure level Value of sound pressure level of a continuous steady sound that, within a measurement time interval T , has the same mean-square sound pressure as a sound under consideration which varies with time, given by

$$L_{\text{peq},T} = 10 \log_{10} \left[\frac{1}{t_2 - t_1} \int_{t_1}^{t_2} \frac{p^2(t)}{p_0^2} dt \right]$$

where t_1 and t_2 are the starting and ending times for the integral, $p(t)$ is the instantaneous sound pressure, p_0 is the reference sound pressure (20 μPa). Also known as *time-averaged sound pressure level*. Unit: decibel (dB). Symbol: $L_{\text{peq},T}$. If the equivalent continuous sound pressure level is A-weighted, then the symbol is $L_{\text{pAeq},T}$, which can be abbreviated as L_{pA} . In general the subscripts "eq" and "T" can be omitted. *See* Sound pressure level, Equivalent continuous A-weighted sound pressure level.

Equivalent sound absorption area (1) Of a room, the hypothetical area of a totally absorbing surface without diffraction effects that, if it were the only absorbing element in the room, would give the same reverberation time as the room under consideration.

Units: square metre (m^2). Symbol: A_1 , for the empty reverberation room; A_2 , for the reverberation room containing a test specimen. *See* Sabin, Eyring absorption coefficient. (2) Of a test specimen, the difference between the equivalent sound absorption area of the reverberation room with and without the test specimen. Units: square metre (m^2). Symbol: A .

Equivalent threshold level For monaural listening, at a specified frequency, for a specified type of transducer, and for a stated force of application of the transducer to the human head, the vibration level, or sound pressure level set up by that transducer in a specified coupler or artificial ear when the transducer is activated by that voltage that, with the transducer applied to the ear concerned, would correspond with the hearing threshold. Unit: decibel (dB). *See* Hearing threshold (1).

Ergodic process A stationary time-dependent stochastic process whose time average is equal to the ensemble average.

Excitation An external force or motion applied to a system that causes the system to respond in some way.

Force excitation The excitation force is independent of the properties of the excited structures; an example of this is the effect of a light and flexible source on a relatively stiff and heavy structure. **Velocity excitation** The excitation velocity is independent of the properties of the excited structures; an example of this is a light and flexible structure excited by a relatively massive source.

Eyring absorption coefficient Sound absorption coefficient attributed to a surface according to the Eyring reverberation time equation

$$T = \frac{24V \ln 10}{-cS \ln(1 - \bar{\alpha})}$$

where V is the volume of the room, in cubic metres; c is the (phase) speed of sound in air, in metres per second; S is the total internal surface area of the room, in square metres. Unit: none. Symbol: $\bar{\alpha}$.

Far field Portion of the radiation field of a sound source in which the sound pressure level decreases by 3 dB for each doubling of the area of the measurement surface. This is equivalent to a decrease of 6 dB for each doubling of the distance from a point source. In the far field, the sound waves can be considered locally planar, and the mean-square pressure is proportional to the total sound power radiated by the source.

Fast Fourier transform (FFT) A rapid numerical technique for computing the discrete Fourier transform. *See* Discrete Fourier transform, Fourier transform.

Fast Hilbert transform A rapid numerical technique for computing the Hilbert transform. The Fourier

transform of the Hilbert transform of $x(t)$ is $H(f) = -j\text{sgn}(f)X(f)$, where $\text{sgn}(f)$ is a sign function, and $X(f)$ is the Fourier transform of $x(t)$. So the fast Hilbert transform can be realized using the fast Fourier transform. *See* Hilbert transform, fast Fourier transform.

Finite element method A numerical approach for obtaining approximate solutions to variational problems. The domain of interest is divided into subdomains referred to as elements. The finite element method uses interpolation functions that satisfy the essential boundary conditions and solves the unknown nodal values that approximately satisfy the governing differential equation over the domain. *See* Boundary element method.

Flanking transmission Sound that travels between a source and a receiving room along paths other than through the partition dividing the two rooms.

Flexibility *See* Compliance.

Force Vector quantity that causes a massive body to accelerate, equal to the time rate of change of momentum of the body. *See* Newton.

Force excitation *See* Excitation.

Forced vibration, forced oscillation Response of a system caused by external excitation. *See* Free vibration.

Formant (1) Noun. A resonance of the vocal tract. The frequencies of the formants are determined in large part by the vocal tract shape; changes in the shape change the frequencies and so result in different speech sounds. *See* Vocal tract. (2) Adjective. A formant synthesizer uses parameters related to the formant frequencies and bandwidths of different speech sounds.

Fourier transform A mathematical operation for decomposing a time function $x(t)$ into its frequency components (amplitude and phase) given by

$$X(f) = \int_{-\infty}^{\infty} x(t)e^{-j2\pi ft} dt$$

The inverse Fourier transform is

$$x(t) = \int_{-\infty}^{\infty} X(f)e^{j2\pi ft} df$$

See Discrete Fourier transform, Spectrum, Fast Fourier transform, Power spectrum.

Free field A sound field in a homogeneous, isotropic medium free of boundaries. In practice, it is a field in which reflections at the boundaries are negligible in the frequency range of interest. *See* Free field over a reflecting plane, Diffuse field.

Free field over a reflecting plane A sound field in a homogeneous, isotropic medium in the half-space above an infinite, rigid plane surface on which the source is located. *See* Free field.

Free vibration, free oscillation A phenomenon that occurs in a mechanical system when it vibrates in the absence of external excitation. Free vibration consists of natural modes of the system, each vibrating at a natural frequency. *See* Forced vibration, Natural frequency, Normal mode of vibration.

Frequency The number of cycles of a periodic phenomenon per unit time interval. It is the reciprocal of the period. Unit: hertz (Hz). Symbol: f . *See* Angular frequency, Period, Hz.

Frequency response function (FRF) Of a linear time-invariant system, the complex ratio of the Fourier transforms of the output signal to the input signal. Mathematically, the frequency response function is the Fourier transform of the impulse response function. By extension, the frequency response function can be used for any two linearly related signals. *See* Impulse response function, Transfer function.

Frequency weighting Modification of the spectrum of an acoustical signal by means of an analog or digital filter having one of the standardized response characteristics known as A, B, C, etc., defined in IEC 61672-1. The A-weighting filter is the one most commonly used. *See* Weighting network.

Fundamental frequency The lowest natural frequency of a dynamic system. *See* Natural frequency.

Ground effect In outdoor sound propagation, the influence of the sound reflected from a surface on horizontal propagation of sound traveling directly from source to receiver. Over distances of 25 m and above, this can be significant at audio frequencies, particularly when reflection at near-grazing angles is involved.

Group speed of sound Travel speed of the energy of a sound wave through a medium, given by $c_g = d\omega/dk$, where ω is the angular frequency, in radians per second; k is the wavenumber, in reciprocal metre. Units: metre per unit time (m/s). Symbol: c_g . *See* Phase speed of sound.

Half-power bandwidth (1) Of a resonance response curve in which the squared gain factor of a linear system is plotted against frequency, the frequency separation between the 3-dB down points on the two sides of the resonance peak, at which the curve is at half of its peak value. (2) Of a signal with a peaked power spectrum, the frequency separation between the points on two sides of the spectral peak where the spectrum level is 3 dB less than the peak value. *See* Bandwidth.

Hand-transmitted vibration Vibration transmitted to the hand, often from powered hand tools.

Harmonic A frequency component whose frequency is an integer multiple of the fundamental frequency of a periodic quantity to which it is related.

Hearing conservation program A system to identify noise-exposed workers, and to monitor their exposure and audiometric function.

Hearing loss Increase in the threshold of audibility due to disease, injury, age, or exposure to intense noise. *See* Presbycusis. **Conductive hearing loss** Hearing loss caused either by blockage of the external ear or by disease or damage in the middle ear, so that the signal amplitude reaching the inner ear is reduced. **Noise-induced hearing loss (NIHL)** Cumulative hearing loss associated with repeated exposure to noise. **Sensorineural hearing loss** Hearing loss due to a lesion or disorder of the inner ear or of the auditory nervous system. **Nonoccupational hearing loss** Hearing loss that is caused by exposures outside of the occupational environment.

Hearing threshold (1) For a given listener and specific signal, the minimum sound pressure level that is capable of evoking an auditory sensation in a specified function of trials. Sound reaching the ears from other sources is assumed to be negligible. *See* Audibility threshold, Masking. (2) The level of a sound at which, under specified conditions, a person gives a predetermined percentage of correct detection responses on repeated trials.

Hearing threshold level (HTL) For a specified signal, amount in decibels by which the hearing threshold for a listener, for either one or two ears, exceeds a specified reference equivalent threshold level. Unit: decibel (dB). *See* Equivalent threshold level, Hearing threshold (1).

Helmholtz resonator Hollow, rigid-walled cavity filled with gas or liquid and having a small opening called the neck. Its fundamental frequency f_0 is approximated by

$$f_0 = \frac{c}{2\pi} \sqrt{\frac{A}{LV}}$$

where c is the (phase) speed of sound, in metres per second, A and L are the cross-sectional area, in square metres and effective length, in metres, of the neck, and V is the cavity volume, in cubic metres. *See* Muffler.

Hertz (Hz) A unit of frequency measurement, representing cycles per second. *See* Frequency.

Hilbert transform A mathematical transform that shifts the phase of each frequency component of the instantaneous spectrum by 90° without affecting the magnitude. For a time signal $x(t)$, its Hilbert transform

is defined as

$$h(t) = H\{x(t)\} = \frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{x(\tau)}{t - \tau} d\tau$$

See Fast Hilbert transform, Fourier transform.

Ideal filter A filter having a rectangularly shaped characteristic: unity amplitude transfer within its passband and zero transfer outside its passband.

Impact Excitation of a structure with a force pulse, for example, by using an impact hammer.

Impact insulation class (IIC) A single number representing 110 dB minus the normalized impact sound index. *See* Normalized impact sound index.

Impact sound pressure level In architectural acoustics, average sound pressure level in a specified frequency band in the receiving room under a test floor being excited by the standardized impact sound source specified in ASTM E492-90. Unit: decibel (dB). *See* Normalized impact sound index, Impact insulation class. **Normalized impact sound pressure level** For a specified frequency band, average sound pressure level in decibels due to the standardized impact sound source, plus 10 times the logarithm to the base 10 of the ratio of the Sabine absorption in the receiving room to the reference Sabine absorption of 10 metric sabins.

Impedance tube A uniform rigid-walled tube with a sound generation device, for example, loudspeaker, at one end to excite plane sound waves. When such a tube is terminated by a sample of material, the acoustic impedance (or the absorption factor) of the material can be determined using a traversing microphone or two fixed microphones. Also known as *standing-wave tube* or *Kundt's tube*.

Impulse response function Of a linear time-invariant system, the function that gives the system output when the input is an impulse function (Dirac's delta function) at time $t = 0$. Its Fourier transform is the frequency response function of the system. For any other type of input, the system output is determined by the convolution between the input and the impulse response function. *See* Frequency response function.

Infrasound Sound at frequencies below the audible range, generally below about 20 Hz.

Insertion loss (1) Of a silencer or other sound reduction element, in a specified frequency band, the decrease in sound pressure level, measured at the location of the receiver, when the sound reduction element is inserted in the transmission path between the source and the receiver. Unit: decibel (dB). (2) Of a silencer or other sound reduction element, in a specified frequency band, the decrease in sound power level, measured when the sound reduction element is

inserted in the transmission path between the source and the receiver. Unit: decibel (dB).

Instantaneous sound intensity Instantaneous rate of flow of sound energy per unit area in the direction of the local instantaneous acoustic particle velocity. This is a vector quantity that is equal to the product of the instantaneous sound pressure at a point and the associated particle velocity: $\mathbf{I}(t) = p(t) \cdot \mathbf{u}(t)$, where $p(t)$ is the instantaneous sound pressure at a point, and $\mathbf{u}(t)$ is the associated particle velocity. Units: watt per square metre (W/m^2). Symbol: $\mathbf{I}(t)$. *See* Sound intensity. *Note:* The sound intensity is generally complex. The real part is the propagating part of the sound field (sometimes called the active part). The imaginary part is the nonpropagating part of the sound field (sometimes called the reactive part).

Integrator A device the output of which is the integrated input. For noise and vibration applications, the integrator is generally an electrical device, used to convert a signal proportional to a vibratory acceleration to one that is proportional to velocity or displacement, or to convert a signal proportional to a vibratory velocity to one that is proportional to displacement.

Intelligibility, speech intelligibility Of speech in a particular listening environment, a qualitative term that describes the ability of the acoustical environment to transmit speech intelligibly, usually expressed relative to perfect listening conditions. Intelligibility can be quantified for a particular speech sample by asking listeners to record their interpretation of what they hear and processing the data to obtain the percentage syllable articulation. *See* Percentage syllable articulation, Articulation index.

Intensity *See* Instantaneous sound intensity, Sound intensity.

Isolation Resistance to the transmission of sound or vibration by materials and structures. **Vibration isolation** Reduction, usually attained by the use of a resilient coupling, in the vibration of a system in response to mechanical excitation.

Jerk A vector quantity that specifies time rate of change of acceleration. Units: metre per second-cubed (m/s^3). *See* Displacement, Velocity, Acceleration.

Leakage *See* Spectral leakage error.

Level Logarithm of the ratio of a powerlike quantity to a reference quantity of the same kind. The base of the logarithm, the reference quantity, and the kind of level shall be specified.

Level difference In architectural acoustics, in a specified frequency band, the difference in the space and time-average sound pressure levels produced in two rooms by one or more sound sources in one of them: $D = L_1 - L_2$, where L_1 is the average sound pressure level in the source room, L_2 is the average

sound pressure level in the receiving room. Also known as *noise reduction*. Unit: decibel (dB). Symbol: D or NR. *See* Sound reduction index. **Standardized level difference** The level difference corresponding to a reference value of the reverberation time in the receiving room, given by $D_{nT} = D + 10 \log_{10}(T/T_0)$, where D is the level difference, T is the reverberation time in the receiving room, and T_0 is the reference reverberation time. Unit: decibel (dB). Symbol: D_{nT} . *Note:* For dwellings, $T_0 = 0.5$ s. The standardizing of the level difference corresponding to the reverberation time in the receiving room of $T_0 = 0.5$ s is equivalent to standardizing the level difference with respect to an equivalent absorption area of $A_0 = 0.32V$, where A_0 is the equivalent absorption area, in square metres, and V is the volume of the receiving room, in cubic metres.

Linearity A characteristic that satisfies the superposition property. (1) Of a system, if two separate inputs x_1 and x_2 produce respective outputs y_1 and y_2 , then the combined input $x_1 + x_2$ produces an output $y_1 + y_2$; if input x produces output y , then input ax (where a is a constant) produces output ay . (2) Of an operator L , it satisfies $L(x_1 + x_2) = L(x_1) + L(x_2)$ and $L(ax) = aL(x)$, where x_1 and x_2 are variables on which the operator L acts, and a is a constant. (3) Of an equation, two solutions can be added, or a solution can be multiplied by a constant, the result is also a solution. *See* Nonlinearity.

Liquid-borne sound Sound that propagates through a liquid. *See* Airborne sound, Structure-borne sound.

Loss factor A measure of the damping capability of a system. For viscous damping, the loss factor is twice the damping ratio. The loss factor may appear in different forms, for example, internal loss factor, radiation loss factor, or coupling loss factor. *See* Damping.

Loudness The attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from soft to loud. *See* Sone, Rating, Magnitude scaling.

Loudness level Of a given sound, the sound pressure level of a reference sound, consisting of a sinusoidal plane progressive wave of frequency 1000 Hz coming from directly in front of the listener, which is judged by otologically normal person to be equally loud to the given sound. Unit: phon. *See* Phon.

Magnitude scaling A method to quantify psychological variables. Typically, a fixed physical stimulus is provided that evokes a perceptual strength to be taken as an internal standard (unit). The subject is requested to assess the ratio of the perceptual strength of an unknown stimulus with respect to that internal standard. *See* Rating, Loudness, Sone.

Masking (1) The process by which the threshold of audibility of one sound is raised by the presence of another (masking) sound. (2) The amount by which

the hearing threshold level is so raised, expressed in decibels.

Mechanical impedance (1) At a surface, the ratio of the total force on the surface to the component of the average sound particle velocity at the surface in the direction of the force. Called driving point impedance if force and velocity are measured at the same point and in the same direction, otherwise called transfer impedance. Units: newton per metre per second [N/(m/s)]. Symbol: Z_m . (2) A form of the inverse frequency response function, which is the complex ratio of the excitation force to the velocity response. *See* Acoustic impedance, Characteristic impedance, Specific acoustic impedance, Mobility.

Microphone Transducer that converts a sensed sound pressure signal to an electric output signal, with minimal distortion over its designed frequency range.

Mobility (1) An alternative term for *mechanical admittance*. (2) The ratio of the following complex quantities:

Mechanical mobility $Z_M = \text{velocity across/}$
force through

Rotational mobility $Z_R = \text{angular velocity across/}$
torque through

Acoustic mobility $Z_A = \text{volume velocity across/}$
sound pressure through

See Admittance, Accelerance, Compliance, Mechanical impedance, Acoustic impedance.

Modal analysis Process of determining the mode shapes and associated parameters, natural frequencies, and damping. **Modal mass** In modal analysis, of a particular mode of a dynamic system, an element in the generalized mass matrix. For mass-normalized mode shapes, the modal mass is unity. **Modal stiffness** In modal analysis, of a particular mode of a dynamic system, an element in the generalized stiffness matrix. For mass-normalized mode shapes, the modal stiffness is equal to the eigenvalue of the characteristic equation of the system. *See* Eigenvalue. **Mode shape** A pattern of vibration exhibited by a structure at a natural frequency. Generally, described as a vector of values, defining the relative displacement amplitudes and phases of each point on the structure at a specified natural frequency. *See* Eigenvector.

Modal density For a given system, the average number of modal resonances per unit interval of frequency. Unit: reciprocal hertz (1/Hz).

Mode of vibration Characteristic pattern assumed by a system undergoing vibration in which the motion of every particle is simple harmonic with the same frequency. *See* Normal mode of vibration.

Mode shape *See* Modal analysis.

Monopole An idealized sound source that is concentrated at a single point in space. A monopole can be

represented by a pulsating sphere producing spherical wave fronts. *See* Dipole, Quadrupole.

Muffler, duct silencer Device designed to reduce the level of sound transmitted along a duct system.

Natural frequency Frequency of free vibration of a system. If the system is damped, then the natural frequency is the damped natural frequency. Unit: hertz (Hz). *See* Damped natural frequency, Eigenvalue, Free vibration.

Near field The portion of the radiation field of a sound source that lies between the source and the far field. *See* Far field.

Neper (Np) A unit of level of a field quantity in terms of logarithm on the Napierian base $e \approx 2.7183$, and unit of level of powerlike quantity when the base of the logarithm is e^2 .

Newton (N) A unit of force. The force of one newton accelerates a 1 kg mass at 1 m/s². *See* Force, Acceleration.

Night average sound pressure level Time-average sound pressure level between 2200 and 0700 hours (9 hours). Unit: decibel (dB). *See* Day average sound pressure level, Day-night sound pressure level, Equivalent continuous sound pressure level.

Node (1) A point, curve, or surface, on a vibrating structure or in a fluid volume that remains stationary. *See* Standing wave. (2) A grid point in the discrete model of a structure.

Noise (1) Undesired, unpleasant sound. *See* Periodic noise, Random noise, Tonal noise, Pink noise, White noise. (2) Erratic, unwarranted disturbance, for example, electrical noise.

Noise dose (1) According to the definition given by Occupational Safety and Health Administration (OSHA), the ratio, expressed as a percentage of (1) the time integral, over a stated time or event, of the 0.6 power of the measured "S" (slow) exponential time-averaged, squared A-weighted sound pressure and (2) the product of the criterion duration (8 hours) and the 0.6 power of the squared sound pressure corresponding to the criterion sound pressure level (90 dB). (2) According to the definition given by the National Institute for Occupational Safety and Health (NIOSH), the percentage of actual exposure relative to the amount of allowable exposure, and for which 100 percent and above represent exposures that are hazardous. The noise dose is calculated using: $D = \sum_{i=1}^n C_i / T_i \times 100\%$, where C_i is the total time of exposure at a specified noise level, and T_i is the exposure time at which noise for this level becomes hazardous.

Noise emission level A-weighted sound pressure level measured at a specified distance and direction from a noise source, in an open environment,

above a specified type of surface. Generally follows the recommendation of a national or industry standard.

Noise exposure forecast (NEF) A complex criterion for predicting future noise impact of airports. The computation considers effective perceived noise level of each type of aircraft, flight profile, number of flights, time of day, etc. Generally used in plots of NEF contours for zoning control around airports. *See* Effective perceived noise level.

Noise exposure level The level given by $L_{EX,8h} = L_{Aeq,T_e} + 10 \log_{10}(T_e/T_0)$, where T_e is the effective duration of the working day, in hours; T_0 is the reference duration (=8 hours); L_{Aeq,T_e} is the A-weighted equivalent sound pressure level during the time interval T_e . If T_e does not exceed 8 hours, $L_{EX,8h}$ is numerically equal to $L_{Aeq,8h}$. Unit: decibel (dB). Symbol: $L_{EX,8h}$. *See* Equivalent continuous A-weighted sound pressure level, Sound exposure. *Note:* The noise exposure level $L_{EX,8h}$ may be calculated from the A-weighted sound exposure E_{A,T_e} , in pascal-squared second ($\text{Pa}^2 \cdot \text{s}$), using the following formula:

$$L_{EX,8h} = 10 \log_{10} \frac{E_{A,T_e}}{1.15 \times 10^{-5}}$$

where the reference sound exposure is $1.15 \times 10^{-5} \text{ Pa}^2 \cdot \text{s}$.

Noise immission level (NIL) A measure of cumulative A-weighted sound exposure during a person's lifetime, based on a modification of the noise exposure level concept. The reference sound exposure is chosen in such a way that after working for N years in an environment with a constant A-weighted sound pressure level L_A , a person who works a typical 1740 hours per year will have a cumulative noise immission level given by $NIL = L_A + 10 \log_{10} N$, assuming that person's leisure time exposure and previously cumulated work exposure are negligible. The equation implies a reference sound exposure of $E_0 = 2.5 \times 10^{-3} \text{ Pa}^2 \cdot \text{s}$, i.e., (1740/8) times the reference sound exposure used for noise exposure level. Unit: decibel (dB). Symbol: NIL. *See* Noise exposure level, Sound exposure level.

Noise reduction coefficient (NRC) Arithmetic average of the sound absorption coefficients of a material at 250, 500, 1000, and 2000 Hz.

Noise reduction (NR) An alternative term for *level difference*. *See* Level difference, Sound reduction index.

Noise reduction rating (NRR) A single-number rating that indicates the noise reduction capabilities of a hearing protector. Unit: decibel (dB).

Noise-induced hearing loss (NIHL) *See* Hearing loss.

Nonlinearity Characteristic that does not satisfy linearity. *See* Linearity.

Normal mode of vibration Mode of free vibration of an undamped system. *See* Eigenvector.

Normal sound intensity Component of the sound intensity in the direction normal to a measurement surface defined by the unit normal vector \mathbf{n} : $I_n = \mathbf{I} \cdot \mathbf{n}$. Units: watt per square metre (W/m^2). Symbol: I_n . *See* Sound intensity.

Normal sound intensity level Logarithmic measure of the unsigned value of the normal sound intensity $|I_n|$, given by: $L_{I_n} = 10 \log_{10} |I_n|/I_0$, where I_0 is the reference sound intensity and is $10^{-12} \text{ W}/\text{m}^2$. When I_n is negative, the level is expressed as $(-)$ XX dB, except when used in the evaluation of residual intensity index. Unit: decibel (dB). Symbol: L_{I_n} . *See* Normal sound intensity, Sound intensity.

Normalized impact sound index (NISI) A single-number rating of normalized impact sound pressure level for 16 successive one-third octave bands from 100 to 3150 Hz inclusive. The calculation procedure is specified in ASTM E989-89. Unit: decibel (dB). *See* Impact sound pressure level, Impact insulation class.

Normalized impact sound pressure level *See* Impact sound pressure level.

Noy A linear unit of noisiness to quantify the annoyance potential of complex sound. *See* Perceived noisiness, Sone.

Nyquist diagram, Nyquist plot A plot of the real part versus the imaginary part of the frequency response function. For a single-degree-of-freedom system, the Nyquist plot is a circle. *See* Argand diagram, Bode diagram, Frequency response function.

Nyquist frequency One-half the sampling frequency in analog-to-digital conversion, which is the theoretical maximum frequency that can be correctly sampled. *See* Sampling theorem, Aliasing error.

Octave A unit of logarithmic frequency interval from f_1 to f_2 , defined as $\log_2(f_2/f_1)$. 1 octave = 0.301 decade. *See* Decade.

Octave band A frequency band whose upper and lower frequency limits are in the ratio of 2. *See* One-third octave band.

Octave filter A filter whose upper and lower passband limits are in the ratio of 2 and centered at one of the preferred frequencies given in ISO 266. Should meet the attenuation characteristic of IEC 61260 and ANSI S1.11-1986.

One-third octave band A frequency band whose upper and lower frequency limits are in the ratio of $2^{1/3}$.

One-third octave filter A filter whose upper and lower passband limits are in the ratio of $2^{1/3}$ and centered at one of the preferred frequencies given in ISO 266. Should meet the attenuation characteristics of IEC 61260 and ANSI S1.11–1986.

Order analysis A form of frequency analysis, used with rotating machines where the amplitudes of signal frequency components are plotted as a function of multiples of the rotational speed. The frequency component with frequency of n times the rotational speed is called the n th order, generally symbolized as nX .

Ototoxic chemical Chemical that causes damage specifically to the cochlea, the auditory nerve, or vestibular system, which impairs the ability to hear. For example, organic solvents, lead, and mercury are ototoxic.

Particle velocity Velocity of a medium particle about its rest positions, usually due to a sound wave. Units: metre per second (m/s).

Pascal (Pa) A unit of pressure corresponding to a force of 1 newton acting uniformly upon an area of 1 square metre. $1 \text{ Pa} = 1 \text{ N/m}^2$.

Passband Of a filter, the frequency range over which the frequency response function has a magnitude close to unity.

Perceived noise level (PNL) A frequency-weighted sound pressure level obtained by a stated procedure that combines the sound pressure levels in the 24 one-third octave bands with midband frequencies from 50 Hz to 10 kHz. Unit: decibel (dB). Symbol: L_{PN} . See Perceived noisiness.

Perceived noisiness, noisiness Prescribed function of sound pressure levels in the 24 one-third octave bands with nominal midband frequencies from 50 Hz to 10 kHz that is used in the calculation of the perceived noise level. Unit: noy. See Noy.

Percentage syllable articulation In a given speech sample presented to a listener, the percentage of syllables that are heard correctly. See Intelligibility, Articulation index.

Percentile level A-weighted sound pressure level obtained by using time-weighting “F” (see IEC 61672-1) that is exceeded for $N\%$ of the time interval considered. Unit: decibel (dB). Symbol: $L_{AN,T}$, for example, $L_{A95,1h}$ is the A-weighted level exceeded for 95% of one hour.

Period The smallest interval (of time or distance) over which an oscillation repeats itself.

Periodic noise A noise event that is periodically repeated. Typical sources of periodic noise are gear wheels and piston machines.

Periodic vibration Oscillatory motion whose amplitude pattern is repeated after fixed increments of time.

Permissible exposure level (PEL) Regulatory limit of sound exposure. The OSHA (Occupational Safety and Health Administration) PEL is a noise dose of 1.0 based on 8-hour A-weighted sound exposure level at 90 dB with a 5 dB exchange rate. European PEL is generally 8-hour A-weighted sound exposure level at 85 dB with a 3-dB exchange rate.

Phase speed of sound Travel speed of the phase of a sound wave through a medium, given by $c = \omega/k$, where ω is the angular frequency, in radians per second; k is the wavenumber, in reciprocal metre. Units: metre per second (m/s). Symbol: c . See Group speed of sound.

Phon Unit of loudness level of a sound. It is numerically equal to the sound pressure level of a 1-kHz free progressive wave that is judged by reliable listeners to be as loud as the unknown sound. See Loudness level.

Phone Acoustic realization of a phoneme. Phones can represent the variation in pronunciation of a phoneme, due to context, dialect, speaking style, or rate, that does not cause a change in meaning. See Phoneme.

Phoneme The minimal sound unit in a language that can change meaning of a word. Each language has its own set of phonemes, which vary both in number of phonemes, from 15 to over 100, and in the sounds included. See Phone.

Pink noise A broadband random noise whose power spectrum is inversely proportional to frequency (-3 dB per octave or -10 dB per decade), thus giving it a constant power spectrum per octave or one-third octave band. See Random noise, White noise.

Power spectrum Magnitude square of frequency spectrum. Also known as *autospectrum*. The power spectrum is real and even. See Autocorrelation function, Power spectrum density, Cross spectrum.

Power spectrum density, power spectral density Limit of the power of a signal (displacement, velocity, acceleration, etc.) divided by bandwidth, as the bandwidth approaches zero. See Power spectrum.

Power spectrum level The level of the power in a band 1 Hz wide referred to a given reference power.

Power unit noise Unwanted sound generated by the propulsion system of a road vehicle, except the tires; such sources including, e.g., engine, air intake, exhaust silencer, transmission, and fan. Other terms sometimes (but incorrectly and inconsistently) used for this include power train noise and drive train noise. Also known as *propulsion noise*. See Tire/road noise.

Preferred frequencies A set of standardized octave and one-third octave center frequencies defined by ISO 266, DIN 45 401, and ANSI S1.6–1967.

Presbycusis, presbycusis Progressive hearing impairment with age, in the absence of other identifiable causes. *See* Hearing loss.

Pressure-residual intensity index Of a sound intensity measurement device, the difference between the indicated sound pressure level L_p and the indicated sound intensity L_I when the device is placed and oriented in a sound field such that the sound intensity is zero: $\delta_{pI_0} = L_p - L_I$. Details for determining the pressure-residual intensity index are given in IEC 61043. Unit: decibel (dB). Symbol: δ_{pI_0} . *See* Dynamic capability index.

Privacy index, speech privacy index (PI) A number that is a measure of speech privacy or lack of speech intelligibility. The privacy index is calculated from the articulation index (AI): $PI = (1 - AI) \times 100\%$. *See* Articulation index.

Quadrupole An idealized sound source consisting of four closely spaced monopoles with adjacent monopoles out-of-phase.

Quality factor, Q factor Of a lightly damped linear system, a measure of the sharpness of a peak in the frequency response, which is equal to the reciprocal of the loss factor of the corresponding vibration mode. *See* Loss factor, Half-power bandwidth.

Radiation efficiency, radiation factor The ratio of the sound power radiated by a vibrating surface, with a given time-mean-square velocity, to the sound power, which would be emitted as a plane wave by the same vibrating surface with the same vibration velocity. The radiation factor is given by the following equation:

$$\sigma = \frac{P_S}{\rho c S_S \bar{v}^2}$$

where P_S is the airborne sound power emitted by the vibrating surface, ρc is the characteristic impedance of air, S_S is the area of the vibrating surface, and \bar{v}^2 is the squared rms value of the vibratory velocity averaged over the area S_S . Unit: none. Symbol: σ . *See* Sound power, Characteristic impedance, Vibratory velocity.

Radiation impedance A generic term for the impedance presented to a vibrating surface by the adjacent acoustical medium. Units: newton per metre per second [N/(m/s)]. Symbol: Z_r . Also known as *fluid loading impedance*. Its real part is the *radiation resistance* from which the emitted sound power is obtained by multiplying it by the mean-square velocity of the body. Symbol: R_r . The imaginary part is called the *radiation reactance*. Symbol: X_r . *See* Acoustic impedance, Mechanical impedance.

Random noise Stationary noise whose instantaneous amplitude cannot be specified at any given instant of time. Instantaneous amplitude can only be defined statistically by an amplitude distribution function. *See* Pink noise, White noise.

Random vibration Vibration whose instantaneous amplitude cannot be specified at any given instant of time. The instantaneous amplitude can only be defined statistically by a probability distribution function that gives the fraction of the total time that the amplitude lies within specified amplitude intervals. Random vibration contains no periodic or quasi-periodic constituents. Pseudo, periodic, and burst random are special forms.

Rating A method to quantify psychological variables, such as annoyance, loudness, and others. Typically, the subject is requested to choose one out of several locations on a scale labeled, for instance, from 0 to 10, whereby the selected location indicates the strength of the internal response. *See* Annoyance, Loudness.

Rayleigh's criterion In thermoacoustics, a necessary condition for the onset of instability, in an irrotational flow at low Mach number that contains a compact heat source of time-varying output $Q(t)$. It states that oscillations can become unstable when the heat input is in phase with the local sound pressure $p(t)$, at any given frequency. A more precise statement applicable to nonlinear oscillation is that instability requires $\oint p(t)Q(t) dt > 0$ (integral over one cycle).

Reactance The imaginary part of an impedance. *See* Acoustic impedance, Mechanical impedance, Resistance.

Reactive sound field Sound field in which the particle velocity is 90° out of phase with the pressure. An ideal standing wave is an example of this type of field, where there is no net flow of energy and constitutes the imaginary part of a complex sound field. *See* Standing wave.

Receptance An alternative term for *dynamic compliance*. *See* Compliance (2).

Reflection coefficient The ratio of the reflected sound pressure amplitude to the pressure amplitude of the sound wave incident on the reflecting object. Unit: none. Symbol: r_a .

Reflection factor, reflectance The ratio of the reflected sound power to the incident sound power. Unit: none. Symbol: r . *See* Absorption factor, Dissipation factor, Transmission factor.

Refraction A phenomenon by which the propagation direction of a sound wave is changed when a wavefront passes from one region into another region of different phase speed of sound.

Repetency *See* Wavenumber.

Resistance The real part of an impedance. *See* Acoustic impedance, Mechanical impedance, Radiation impedance, Reactance.

Resolution The smallest change or amount a measurement system can detect.

Resonance Conditions of peak vibratory response where a small change in excitation frequency causes a decrease in system response.

Resonance frequency Frequency at which resonance exists. Unit: Hz.

Response Motion or other output resulting from an excitation, under specified conditions. *See* Excitation.

Reverberant sound field Portion of the sound field in the test room over which the influence of sound received directly from the source is negligible.

Reverberation Persistence of sound in an enclosure after a sound source has stopped.

Reverberation room A room with low absorption and long reverberation time, designed to make the sound field therein as diffuse as possible.

Reverberation time Of an enclosure, for a given frequency or frequency band, the time required for the sound pressure level in an initially steady sound field to decrease by 60 dB after the sound source has stopped. Unit: second (s).

Room constant A quantity used to describe the capability of sound absorption of an enclosure, determined by $R = S\bar{\alpha}/(1 - \bar{\alpha})$, where S is the total internal surface area of the enclosure, in square metres; $\bar{\alpha}$ is the average sound absorption coefficient of the enclosure. Units: square metre (m^2). Symbol: R .

Root mean square (rms) The square root of the arithmetic average of a set of squared instantaneous values.

Sabin, metric sabin A measure of sound absorption of a surface. One metric sabin is equivalent to 1 square metre of perfectly absorptive surface. *See* Absorption, Equivalent sound absorption area.

Sampling theorem Theorem that states that if a continuous time signal is to be completely described, the sampling frequency must be at least twice the highest frequency present in the original signal. Also known as *Nyquist theorem*, *Shannon sampling theorem*.

Scaling *See* Magnitude scaling, Rating.

Semianechoic field *See* Free field over a reflecting plane.

Semianechoic room A test room with a hard, reflecting floor whose other surfaces absorb essentially all the incident sound energy over the frequency range of interest, thereby affording free-field conditions above a reflecting plane. *See* Anechoic room, Free field over a reflecting plane.

Sensitivity (1) Of a linear transducer, the quotient of a specified quantity describing the output signal by another specified quantity describing the corresponding input signal, at a given frequency. (2) Of a data acquisition device or spectrum analyzer, a measure of the device's ability to display minimum level signals. (3) Of a person, with respect to a noise, the extent of being annoyed.

Sensorineural hearing loss *See* Hearing loss.

Shock Rapid transient transmission of mechanical energy.

Shock spectrum Maximum acceleration experienced by a single-degree-of-freedom system as a function of its own natural frequency in response to an applied shock.

Signal-to-noise ratio (SNR) In a signal consisting of a desired component and an uncorrelated noise component, the ratio of the desired-component power to the noise power. For a signal $x(t)$, if $x(t) = s(t) + n(t)$, where $s(t)$ is the desired signal, and $n(t)$ is noise, then the signal-to-noise ratio is defined as $\text{SNR} = 10 \log_{10} \langle s^2 \rangle / \langle n^2 \rangle$, where $\langle \rangle$ indicates a time average.

Significant threshold shift Shift in hearing threshold, outside the range of audiometric testing variability (± 5 dB), that warrants followup action to prevent further hearing loss. The National Institute of Occupational Safety and Health (NIOSH), defines significant threshold shift as an increase in the hearing threshold level of 15 dB or more at any frequency (500, 1000, 2000, 3000, 4000, or 6000 Hz) in either ear that is confirmed for the same ear and frequency by a second test within 30 days of the first test. *See* Hearing threshold level.

Silencer Any passive device used to limit noise emission.

Simple harmonic motion Periodic motion whose displacement varies as a sinusoidal function of time.

Single-event sound pressure level Time-integrated sound pressure level of an isolated single sound event of specified duration T (or specified measurement time T) normalized to $T_0 = 1$ s. It is given by the formula:

$$L_{p,ls} = 10 \log_{10} \left[\frac{1}{T_0} \int_0^T \frac{p^2(t)}{p_0^2} dt \right] \\ = L_{peq,T} + 10 \log_{10} \left(\frac{T}{T_0} \right) \text{ dB},$$

where $p(t)$ is the instantaneous sound pressure, p_0 is the reference sound pressure, and $L_{peq,T}$ is the equivalent continuous sound pressure level. Unit: decibel (dB). Symbol: $L_{p,ls}$.

Sone A linear unit of loudness. One sone is the loudness of a pure tone presented frontally as a

plane wave of 1000 Hz and a sound pressure level of 40 dB, referenced to 20 μPa . *See* Loudness, Magnitude scaling.

Sound Energy that is transmitted by pressure waves in air or other materials and is the objective cause of the sensation of hearing. Commonly called noise if it is unwanted.

Sound absorption coefficient *See* Absorption factor.

Sound energy density Mean sound energy in a given volume of a medium divided by that volume. If the energy density varies with time, the mean shall be taken over an interval during which the sound may be considered statistically stationary. Units: joule per cubic metre (J/m^3).

Sound energy, acoustic energy Total energy in a given volume of a medium minus the energy that would exist in that same volume with no sound wave present. Unit: joule (J).

Sound exposure Time integral of squared, instantaneous sound pressure over a specified interval of time,

given by $E = \int_{t_1}^{t_2} p^2(t) dt$, where $p(t)$ is the instantaneous sound pressure, t_1 and t_2 are the starting and ending times for the integral. If the instantaneous sound pressure is frequency weighted, the frequency weighting should be indicated. Units: pascal-squared second (Pa^2s). Symbol: E . *See* Sound pressure.

A-weighted sound exposure Exposure given by $E_{A,T} = \int_{t_1}^{t_2} p_A^2(t) dt$, where $p_A(t)$ is the instantaneous A-weighted sound pressure of the sound signal integrated over a time period T starting at t_1 and ending at t_2 . *See* Frequency weighting.

Sound exposure level (SEL) Measure of the sound exposure in decibels, defined as $L_E = 10 \log_{10}(E/E_0)$ dB, where E is sound exposure, and the reference value $E_0 = 400 \mu\text{Pa}^2 \text{ s}$. Unit: decibel (dB). Symbol: L_E . *See* Sound exposure, Single-event sound pressure level.

Sound intensity Time-averaged value of the instantaneous sound intensity $\mathbf{I}(t)$ in a temporally stationary sound field:

$$\mathbf{I} = \frac{1}{t_1 - t_2} \int_{t_1}^{t_2} \mathbf{I}(t) dt$$

where t_1 and t_2 are the starting and ending times for the integral. Units: watt per square metre (W/m^2). Symbol: \mathbf{I} . *See* Instantaneous sound intensity. *Note:* Sound intensity is generally complex. The symbol J is often used for complex sound intensity. The symbol I is used for active sound intensity, which is the real part of a complex sound intensity.

Sound intensity level A measure of the sound intensity in decibels, defined as $L_I = 10 \log_{10}(I/I_0)$, where I is the active sound intensity, and the reference value $I_0 = 10^{-12} \text{W/m}^2 = 1 \text{ pW/m}^2$. Unit: decibel (dB).

Sound level *See* Sound pressure level.

Sound level meter Electronic instrument for measuring the sound pressure level of sound in accordance with an accepted national or international standard. *See* Sound pressure level.

Sound power Power emitted, transferred, or received as sound. Unit: watt (W). *See* Sound intensity.

Sound power level (SPL) Ten times the logarithm to the base 10 of the ratio of a given sound power to the reference sound power, given by $L_W = 10 \log_{10}(P/P_0)$, where P is the rms value of sound power in watts, and the reference sound power P_0 is 1 pW ($= 10^{-12} \text{ W}$). Unit: decibel (dB). Symbol: L_W . The weighting network or the width of the frequency band used should be indicated. If the sound power level is A-weighted, then the symbol is L_{WA} . *See* Frequency weighting.

Sound pressure Dynamic variation in atmospheric pressure. Difference between the instantaneous pressure and the static pressure at a point. Unit: pascal (Pa). Symbol: p . **A-weighted sound pressure** The root-mean-square sound pressure determined by use of frequency weighting network A (see IEC 61672-1). Symbol: p_A .

Sound pressure level (SPL) Ten times the logarithm to the base 10 of the ratio of the time-mean-square sound pressure to the square of the reference sound pressure, given by $L_p = 10 \log_{10}(p^2/p_0^2)$, where p is the rms value (unless otherwise stated) of sound pressure in pascals, and the reference sound pressure p_0 is 20 μPa ($= 20 \times 10^{-6} \text{ N/m}^2$) for measurements in air. Unit: decibel (dB). Symbol: L_p . If p denotes a band-limited, frequency or time-weighted rms value, the frequency band used or the weighting shall be indicated. Frequency and time weightings are specified in IEC 61672-1. **A-weighted sound pressure level** Sound pressure level of A-weighted sound pressure, given by $L_{pA} = 10 \log_{10}(p_A^2/p_0^2)$, where p_A is the A-weighted sound pressure, and p_0 is the reference sound pressure. Symbol: L_{pA} . *See* Sound pressure. **Band pressure level** The sound pressure level in a particular frequency band.

Sound reduction index Of a partition, in a specified frequency band, 10 times the logarithm to the base 10 of the reciprocal of the sound transmission coefficient, given by $R = 10 \log_{10}(1/\tau) = 10 \log_{10}(W_1/W_2)$, where τ is the sound transmission coefficient, W_1 is the sound power incident on the partition under test, and W_2 is the sound power transmitted through the specimen. In practice, the sound reduction

index is evaluated from

$$R = L_1 - L_2 + 10 \log_{10} \frac{S}{A} = D + 10 \log_{10} \frac{S}{A}$$

where L_1 and L_2 are the average sound pressure levels in the source and receiving rooms, S is the area of the test specimen, A is the equivalent sound absorption area in the receiving room, and D is the level difference. Also known as *sound transmission loss*. Unit: decibel (dB). Symbol: R , or TL. *See* Sound transmission coefficient, Level difference, Equivalent sound absorption area, Coincidence effect. **Apparent sound reduction index** Ten times the logarithm to the base 10 of the ratio of the sound power W_1 , which is incident on the partition under test to the total sound power transmitted into the receiving room if, in addition to the sound power W_2 transmitted through the specimen, the sound power W_3 transmitted by flanking elements or by other components, is significant:

$$R' = 10 \log_{10} \left(\frac{W_1}{W_2 + W_3} \right)$$

Unit: decibel (dB). Symbol: R' . *See* Flanking transmission.

Sound source Anything that emits acoustic energy into the adjacent medium.

Sound transmission class (STC) A single-number rating for describing sound transmission loss of a wall or partition. Unit: decibel (dB). The standardized method of determining sound transmission class is provided in ASTM E413-87. *See* Sound reduction index.

Sound transmission loss *See* Sound reduction index.

Sound volume velocity Surface integral of the normal component of the sound particle velocity over an area through which the sound propagates. Also known as *sound volume flow rate*. Units: cubic metre per second (m^3/s). Symbol: q or q_v .

Sound energy flux Time rate of flow of sound energy through a specified area. Unit: watt (W).

Specific acoustic impedance Complex ratio of sound pressure to particle velocity at a point in an acoustical medium. Units: pascal per metre per second [$\text{Pa}/(\text{m}/\text{s})$], or rayls ($1 \text{ rayl} = 1 \text{ N} \cdot \text{s}/\text{m}^3$). *See* Characteristic impedance, Acoustic impedance, Mechanical impedance.

Specific airflow resistance A quantity defined by $R_s = RA$, where R is the airflow resistance, in pascal seconds per cubic metre, of the test specimen, and A is the cross-sectional area, in square metres, of the test specimen perpendicular to the direction of flow. Units: pascal second per metre ($\text{Pa} \cdot \text{s}/\text{m}$). Symbol: R_s . *See* Airflow resistance.

Spectral leakage error In digital spectral analysis, an error that the signal energy concentrated at a particular frequency spreads to other frequencies. This phenomenon results from truncating the signal in the time domain. The leakage error can be minimized by applying a proper window to the signal in the time domain. *See* Window.

Spectrum Description of a signal resolved into frequency components, in terms of magnitude, and sometimes as well as phase, such as power spectrum, one-third octave spectrum. *See* Fourier transform, Power spectrum, Power spectrum density, Cross spectrum.

Speech quality Degree to which speech sounds normal, without regard to its intelligibility. Measurement is subjective and involves asking listeners about different aspects of speech such as naturalness, amount and type of distortion, amount and type of background noise.

Standard threshold shift Increase in the average hearing threshold of 10 dB or more at 2000, 3000, and 4000 Hz in either ear. *See* Hearing loss, Hearing threshold.

Standardized level difference *See* Level difference.

Standing wave Periodic wave motion having a fixed amplitude distribution in space, as the result of superposition of progressive waves of the same frequency and kind. Characterized by the existence of maxima and minima amplitudes that are fixed in space.

Static pressure Pressure that would exist in the absence of sound waves.

Statistical pass-by (SPB) method A measurement method used for measuring noise properties of road surfaces (pavements), utilizing a roadside microphone (7.5 m from the center of the road lane being measured) and speed measurement equipment. Vehicles passing by in the traffic are measured and classified according to standard types, provided no other vehicles influence the measurement. The measured values are treated statistically, by vehicle type; being plotted as noise level versus speed. Either the regression curve is determined or the noise level is read at one or a few reference speeds. The method is standardized as ISO 11819-1. *See* Tire/road noise, Close-proximity method.

Stiffness The ratio of the change in force to the corresponding change in displacement of an elastic element, both in specified direction.

Structure-borne sound Sound that propagates through a solid structure. *See* Airborne sound, Liquid-borne sound.

Subharmonic A frequency component whose frequency is an integer fraction of the fundamental frequency of a periodic quantity to which it is related. *See* Harmonic.

Susceptance The imaginary part of an admittance. *See* Admittance, Conductance.

Swept sine A test signal consisting of a sine wave whose frequency is changing according to a certain pattern, usually a linear or logarithmic progression of frequency as a function of time, or an exponential sweep.

Thermoacoustical excitation Excitation of sound wave by periodic heat release fluctuations of a reacting flow (flame). A necessary condition for thermoacoustical excitation is given by the Rayleigh criterion. *See* Rayleigh criterion.

Time-averaged sound pressure level An alternative term for *equivalent continuous sound pressure level*. *See* Equivalent continuous sound pressure level.

Time-weighted average (TWA) The averaging of different exposure levels during an exposure period. For noise, given an A-weighted 85-dB sound exposure level limit and a 3-dB exchange rate, the TWA is calculated using: $TWA = 10 \log_{10}(D/100) + 85$, where D is the noise dose. *See* Noise dose (2).

Tire/road noise Unwanted sound generated by the interaction between a rolling tire and the surface on which it is rolling. Also known as *tire/pavement noise*. *See* Close-proximity method, Statistical pass-by method.

Tonal noise Noise dominated by one or several distinguishable frequency components (tones).

Transducer A device designed to convert an input signal of a given kind into an output signal of another kind, usually electrical.

Transfer function Of a linear time-invariant system, the ratio of the Fourier or Laplace transform of an output signal to the same transform of the input signal. *See* Frequency response function.

Transmissibility The ratio of the response amplitude of a system in steady-state forced vibration to the excitation amplitude. The input and output are required to be of the same type, for example, force, displacement, velocity, or acceleration.

Transmission factor, transmission coefficient, transmittance The ratio of the transmitted sound power to the incident sound power. Unit: none. Symbol: τ . *See* Absorption factor, Dissipation factor, Reflection factor.

Transmission loss (1) Reduction in magnitude of some characteristic of a signal between two stated points in a transmission system, such as a silencer. The characteristic is often some kind of level, such as power level or voltage level. Transmission loss is usually in units of decibels. It is imperative that the characteristic concerned (such as sound pressure level) be clearly identified because in all transmission

systems more than one characteristic is propagated. (2) An equivalent term for *sound transmission loss*. *See* Sound reduction index. (3) In underwater acoustics, between specified source and receiver locations, the amount by which the sound pressure level at the receiver lies below the source level. Also known as *propagation loss*.

Turbulence A fluid mechanical phenomenon that causes fluctuation in the local sound speed relevant to sound generation in turbo machines (pumps, compressors, fans, and turbines), pumping and air-conditioning systems, or propagation from jets and through the atmosphere.

Ultrasound Sound at frequencies above the audible range, i.e., above about 20 kHz.

Velocity A vector quantity that specifies time rate of change of displacement. Units: metre per second (m/s). *See* Displacement, Acceleration, Jerk, Particle velocity, Vibratory velocity.

Velocity excitation *See* Excitation.

Vibration (1) Oscillation of a parameter that defines the motion of a mechanical system. Vibration may be broadly classified as transient or steady state, with further subdivision into either deterministic or random vibration. (2) The science and technology of vibration. *See* Forced vibration, Free vibration.

Vibration absorber A passive subsystem attached to a vibrating machine or structure in order to reduce its vibration amplitude over a specified frequency range. At frequencies close to its own resonance, the vibration absorber works by applying a large local mechanical impedance to the main structure. Also known as *vibration neutralizer*, *tuned damper*.

Vibration isolator A resilient support that reduces vibration transmissibility. *See* Isolation, Transmissibility.

Vibration meter An instrument for measuring oscillatory displacement, velocity, or acceleration.

Vibration severity A criterion for predicting the hazard related to specific machine vibration levels.

Vibratory velocity level, vibration velocity level Velocity level given by the following formula $L_v = 10 \log_{10}(v^2/v_0^2)$, where v is the rms value of the vibratory velocity within the frequency band of interest, v_0 is the reference velocity and is equal to 5×10^{-8} m/s (as specified in ISO 7849) or 10^{-9} m/s (as specified in ISO 1683). Unit: decibel (dB). Symbol: L_v . *See* Vibratory velocity.

Vibratory velocity, vibration velocity Component of the velocity of the vibrating surface in the direction normal to the surface. The root-mean-square value of the vibratory velocity is designated by the symbol v . *See* Vibratory velocity level.

Viscosity Of a fluid, in a wide range of fluids the viscous stress is linearly related to the rate of strain; such fluids are called *newtonian*. The constant of proportionality relating fluid stress and rate of strain is called the viscosity. Units: pascal seconds (Pa·s).

Vocal folds, vocal cords Paired muscular folds of tissue layers inside the larynx that can vibrate to produce sound.

Vocal tract Air passage from the vocal folds in the larynx to the lips and nostrils. It can be subdivided into the pharynx, from larynx to velum, the oral tract, from velum to lips, and the nasal tract, from above the velum through the nasal passages to the nostrils. Its shape is the main factor affecting the acoustical characteristics of speech sounds. *See* Vocal folds.

Voicing, voiced, voiceless, unvoiced, devoiced Voicing is one of the three qualities by which speech sounds are classified; a sound with voicing is called voiced, which means that the vocal folds are vibrating and produce a quasi-periodic excitation of the vocal tract resonances. A phoneme that is normally voiced but is produced without voicing, or in which the voicing ceases, is devoiced. A phoneme that is intended not to be voiced is voiceless or unvoiced. *See* Vocal folds, Phoneme.

Voltage preamplifier A preamplifier that produces an output voltage proportional to the input voltage from a piezoelectric transducer. Input voltage depends upon cable capacitance.

Volume velocity (1) *See* Sound volume velocity. (2) For speech, a measure of flow rate in the absence of sound, as through a duct, including through the vocal tract. Units: cubic metre per second (m³/s).

Wavefront (1) For a progressive wave in space, the continuous surface that is a locus of points having the same phase at a given instant. (2) For a surface wave, the continuous line that is a locus of points having the same phase at a given instant.

Wavelength Distance in the direction of propagation of a sinusoidal wave between two successive points

where at a given instant of time the phase differs by 2π . Equals the ratio of the phase speed of sound in the medium to the fundamental frequency.

Wavenumber At a specified frequency, 2π divided by wavelength, or angular frequency divided by the phase speed of sound: $k = 2\pi/\lambda = \omega/c$, where λ is wavelength, in metres; ω is angular frequency, in radians per second; c is the phase speed of sound, in metres per second. Unit: reciprocal metre (1/m). Symbol: k . *Notes:* (1) The ISO standards prefer to use the term *angular repetency* and *repetency*. A remark in ISO 8000 says that in English the names repetency and angular repetency should be used instead of wavenumber and angular wavenumber, respectively, since these quantities are not numbers. (2) Angular repetency is defined as the same as wavenumber. (3) Repetency: at a specified frequency, the reciprocal of wavelength: $\sigma = 1/\lambda$, where λ is wavelength. Unit: reciprocal metre (1/m). Symbol: σ .

Weighting (1) *See* Frequency weighting. (2) *See* Window. (3) Exponential or linear time weighting defined in IEC 61672-1.

Weighting network Electronic filter in a sound level meter that approximates under defined conditions the frequency response of the human ear. The A-weighting network is most commonly used. *See* Frequency weighting.

White noise A noise the power spectrum of which is essentially independent of frequency. *See* Pink noise.

Whole-body vibration Vibration of the human body as a result of standing on a vibrating floor or sitting on a vibrating seat. Often encountered near heavy machinery and on construction equipment, trucks, and buses.

Window In signal processing, a weighting function with finite length applied to a signal. Usually applied in the time domain, as a multiplying function applied to the time signal. For spectral analysis, Hanning, Hamming, triangle, Blackman, flat top, Kaiser windows are commonly used. Force and exponential windows are special for impact testing.
